

Long-Distance Trade and Long-Term Persistence*

Sebastian Ellingsen

Abstract

Do changes in the location of trading opportunities lead to changes in the location of economic activity? This paper explores this question using a staggered lifting of restrictions on direct trade with Europe across the Spanish Empire in the 18th century. I combine a difference-in-differences approach with a dynamic spatial equilibrium framework and detailed georeferenced data on maritime travel from historical logbooks to examine this issue. I find that the reform improved market integration and induced urban growth, but had a smaller effect in locations with larger internal markets. Moreover, I show that modern-day settlement patterns depend less on the pre-reform settlement pattern in areas affected by the reform. Taken together, the findings provide evidence that the location of economic activity adapts to changes in the location of trading opportunities, but can persist when these changes are preceded by urban growth.

1 Introduction

What determines the location of economic activity? Historical patterns of trade are widely recognized to play an important role by shaping the emergence and growth of cities. The growth of many of the world's largest cities was initiated by access to long-distance trade, but have long ceased to be important trading locations. Do historical patterns of trade dictate the location and size of cities today despite the marked change in patterns of trade? Or does the location of economic activity adapt to changes in the location of trading opportunities? If so, under what conditions?

To seek answers to these questions, I exploit a large-scale historical experiment: the expansion of direct trade with Europe in the Spanish Empire during the 18th century. Early Spanish commercial policy restricted the direct trade of goods with Europe. However, driven by political developments in Europe and dynastic changes in Spain, these restrictions were gradually lifted in the second half of the 18th century. While only four ports were permitted to trade goods directly with Europe in 1765, this number had increased to 45 by the beginning of the 19th century. By this time, no major ports in the empire were subject to restrictions on the direct trade of goods with Europe (see Figure 1).

This paper is based on a large collection of data to construct a novel dataset of cities, settlements, shipping times, and trade for the Spanish Empire in the 18th and 19th centuries. To quantify how the reform affected empire-wide shipping times, I construct a directed network of trade costs. For maritime shipping, I estimate sailing speeds based on historical maritime logbooks and georeferenced data on wind patterns. To estimate travel speed on land, I account for key geographic factors that historically shaped mobility, such as the slope, elevation, landcover, and the location of roads and ports. This approach results in time-varying bilateral trade cost matrices between all locations in the sample, which I validate using a range of historical and contemporary sources. These time-varying measures of bilateral shipping times are then matched with data on geographical characteristics, agricultural productivity, urban populations, and the locations of settlements to construct a balanced panel covering Spanish America during the 18th and 19th centuries.

I leverage this variation using a difference-in-differences approach, comparing changes in population growth in cities where trade costs changed differentially because of the reform. The identification assumption is that changes in population growth in such locations would have been the same in the absence of the reform. I challenge this assumption in several ways and provide evidence in support of a causal interpretation of the estimates. The variation is well suited to study the research questions for several reasons. First, while the reform caused large and spatially heterogeneous variation in international trade costs, these changes were limited to the costs of trading goods. Second, the geographic scope of the reform allows me

to consider its heterogeneous effects while keeping other long-run determinants of growth, such as formal institutions and legal origins, fixed. Finally, compared to studies of single countries or regions, the geographic scope of this setting is compelling in terms of external validity.

I document four main results. First, I show that the reform improved market integration between Europe and America. While the shipping time was 6 days lower on average, the decrease ranges from 0 to 27 days.¹ Second, I find that improved access to maritime trade increased urban growth and induced the formation of new settlements. In the preferred specification, a one standard deviation reduction in the shipping time (6.5 days) increases the urban population growth rate by around 8 percentage points. Third, I show that the effects are concentrated in less populous cities and regions. Finally, consistent with these patterns, I show that the correlation between pre-reform and contemporary population density is lower in areas more intensively treated by the reform. Taken together, the findings provide evidence that the location of economic activity adapted to the change in the location of trading opportunities. However, this adaptation occurred to a greater extent in locations with smaller internal markets, thus weakening the persistence of pre-reform settlement patterns.

To explore potential mechanisms driving these results as well as the long-term implications, I interpret the findings through the lens of a parsimonious dynamic spatial general equilibrium model that I calibrate to match the observed data.² The model is consistent with key features of the historical context. In the model, the population can move freely among cities that differ in their productivity, their access to trade, and their availability of arable land which determines the urban carrying capacity. The pre-reform location of trading opportunities can continue to shape the location of economic activity by giving rise to self-sustained concentrations of economic activity. Alternatively, the continued impact can reflect a slow convergence to a new equilibrium. Crucially, the model allows for the consideration of both these mechanisms by incorporating dynamic agglomeration economies following [Allen and Donaldson \(2020\)](#). As a result, the locational fundamentals therefore potentially depend on both the contemporaneous and historical population size.

Estimating the model, I find evidence of positive dynamic agglomeration externalities. The model therefore accounts for the reduced-form findings and provides several additional insights. The model highlights that the reform induced population growth by lowering the price of traded goods, but that it had a smaller effect on the cost of living in locations with larger home markets. Moreover, the model shows that changes in trade costs attenuated the

¹The calculated travel times are validated with several historical and contemporary datasets. For example, I provide evidence that the calculated sailing times are highly correlated with mail dispatch times and recorded travel times in the 18th century.

²The model builds on recent quantitative models of trade and geography, which accommodate a large number of locations that are asymmetric in their locational characteristics and frictions to trade and migration ([Redding and Rossi-Hansberg, 2017](#)).

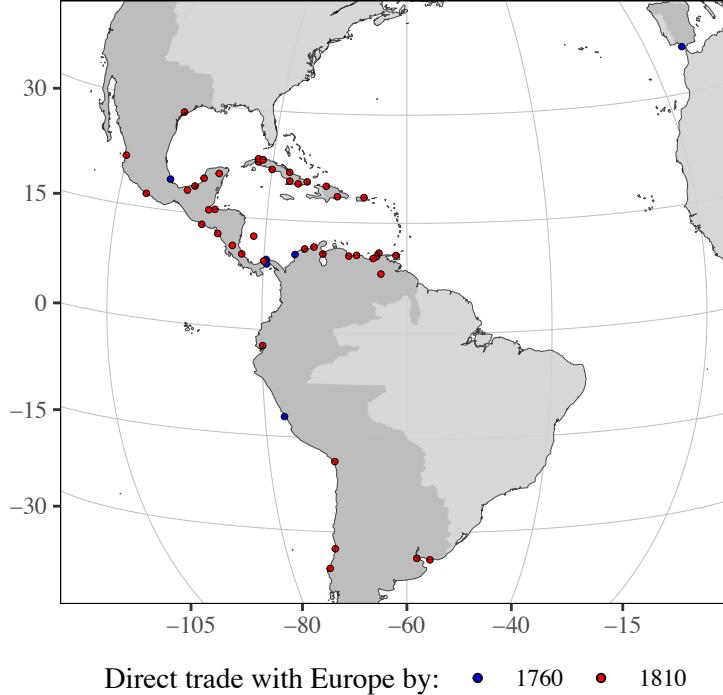

Figure 1: This map depicts the extent of the territory claimed by the Spanish Empire in 1790 with its ports marked according to status. Ports marked in blue were licensed for direct trade with Europe before 1765 (Callao, Cartagena, Veracruz, and Panama), while those marked in red were licensed to trade with Europe in 1810.

persistence of the pre-reform settlement pattern by disproportionately increasing economic growth in smaller cities. Finally, the model sheds light on the source of persistence of the pre-reform settlement pattern. In particular, because the spatial distribution of economic activity is uniquely determined by fundamentals, the persistence of pre-reform settlements is driven not by self-sustaining agglomerations arising around central pre-reform trading locations, but by a gradual convergence to the new steady-state. In conclusion, the findings provide evidence that the location of economic activity adapts to changes in the location of trading opportunities, but can persist when such changes are preceded by urban growth.

This paper contributes to the literature on history dependence in urban economics and economic geography. History dependence in the location of economic activity is consistent with the persistent impact of locational advantages (Davis and Weinstein, 2002; Maloney and Valencia, 2016; Bosker and Buringh, 2017; Alix-Garcia and Sellars, 2020; Bakker et al., 2021) and multiple spatial equilibria (Krugman, 1991a; Redding, Sturm and Wolf, 2010; Bleakley and Lin, 2012; Michaels and Rauch, 2018). While persistence in the spatial distribution of economic activity is well-documented, little is known about what drives differences in the degree of persistence across locations. This is puzzling because Henderson et al. (2018) show that the importance of historical locational advantages differs substantially across countries. This paper contributes to the literature by shedding light on the conditions under which history matters for the location of economic activity and by establishing a relationship

between persistence and international trade costs. The paper therefore builds on a body of literature emphasizing the importance of international trade in shaping economic geography within countries. Earlier contributions emphasized the role of trade openness in determining spatial concentration in stylized settings (Henderson, 1982; Ades and Glaeser, 1995; Krugman and Elizondo, 1996), while later studies have explored the effect of trade on a range of outcomes in models accommodating rich geographies (Redding and Sturm, 2008; Fajgelbaum and Redding, 2014; Coşar and Fajgelbaum, 2016; Nagy, 2018). This paper builds on this literature by exploring the long-run effects of changes in the location of trading opportunities and the role of trade in shaping persistence in the location of economic activity.

This paper also contributes to the literature that explores the long-term economic impacts of historical institutions in general, (Acemoglu, Johnson and Robinson, 2001, 2002; Nunn, 2008; Dell, 2010) and the economic legacy of the Spanish Empire in particular (Grafe and Irigoin, 2006, 2012; Bruhn and Gallego, 2011; Engerman et al., 2012; Valencia, 2019). Acemoglu, Johnson and Robinson (2002) establish a negative relationship between population densities in 1500 and today. They show that lower initial population density necessitated institutions that enabled broader participation in the economy. These institutions were in turn conducive to sustained economic growth and therefore contributed to a divergence between areas with different initial densities, which began in the second half of the 18th century. Other important contributions to the literature have emphasized the role of migration from Europe in generating this reversal (Chanda, Cook and Putterman, 2014; Easterly and Levine, 2016). This paper complements these findings by highlighting the role of trade-related institutions. The results are consistent with the view that the *reversal of fortune* in the Americas is rooted in institutional change, while highlighting the importance of the factors that shaped institutions governing trade, such as the transition from Habsburg to Bourbon rule in Spain. More broadly, this paper provides evidence of the impact of trade-related institutions on economic growth, which has received little attention in the literature (Jha, 2013; Jia, 2014; Alvarez-Villa and Guardado, 2020).

Finally, the findings contribute to the empirical literature on the effects of international trade on economic development. The literature using reduced-form approaches has documented sizeable impacts of trade on national income (Frankel and Romer, 1999; Feyrer, 2009, 2019; Maurer and Rauch, 2019), while papers relying on structural approaches have found more modest positive effects (Arkolakis, Costinot and Rodríguez-Clare, 2012). However, studying the diffusion of steamship technology in the late 19th century, Pascali (2017) finds little evidence that trade integration promotes economic development, except in countries with inclusive institutions. This is consistent with increased access to trade inducing some countries to specialize in sectors that have fewer growth-enhancing externalities (Grossman and Helpman, 1990), are more volatile (Blattman, Hwang and Williamson, 2007), have weaker

economies of scale (Matsuyama, 1992; Krugman and Venables, 1995), or have negative effects on institutions (Acemoglu, Johnson and Robinson, 2005; Puga and Trefler, 2014). The findings in this paper complement this literature by providing evidence that trade can promote economic development *within* countries even in countries with highly extractive institutions. Relatedly, this paper contributes to the debates on the sources of the growth in world trade in the 19th century (Estevadeordal, Frantz and Taylor, 2003) and on the role of the breakdown of mercantilist policies (O'Rourke and Williamson, 2002; O'Rourke, 2006). Previous efforts to examine this relationship have been constrained by a lack of historical trade data. I contribute to this literature by providing direct empirical evidence of the importance of the breakdown of monopolies controlling long-distance trade for economic growth and market integration.

This paper is structured as follows. Section 2 presents the historical background. Section 3 presents the data sources. Section 4 provides details on the calculation of trade costs. Section 5 elaborates on the reduced-form research design and main results. Section 6 presents the model and the proposed mechanisms. Section 7 concludes.

2 Historical Background

This section provides the historical background for the analysis. I outline the institutional setting, the motivation for the trade reform as well as the historical relationship between trade and economic development within the Spanish Empire in America.

The Spanish commercial system. A central aim of commercial policy in the 18th century was to promote state wealth acquisition through trade surpluses (Findlay and O'Rourke, 2007). In the Spanish context, this was achieved through a range of policies restricting trade. First, trade was restricted to four ports in the Americas (Cartagena de Indias, Callao, Portobello/Nombre de Dios, and Veracruz) and only Seville (later Cadiz) in Europe. Further, the frequency of travel and the routes were restricted.³ Third, participation in Atlantic trade was restricted to Spanish merchants. Finally, there were high tax rates on imports and exports.⁴ These measures effectively monopolized trade in the merchant guilds in Seville (later Cadiz), Mexico City, and Lima. These cities in turn managed trade with other locations in their respective viceroyalties, typically transported by third parties using mule trains (*recuas*) or wagons (*carros*) depending on the road conditions.

³Typically, only two fleets left Spain every year: the New Spain *flota* destined for Veracruz, and the *Tierra Firme galeones* destined for Cartagena and Portobello. In the Pacific, shipping was conducted by *Armada del Sur*, which carried goods from the trade fairs in Portobello to Pacific ports in South America (Walker, 1979). Moreover, the Manilla galleon would sail between Acapulco and Manilla. Official information was carried by *aviso* ships, which were light carriers operating separately from the commercial system and were not permitted or equipped to carry freight.

⁴The duties typically depended on the origin of the goods, with lower rates on goods originating from Spain.

The system limited trade with Europe across large parts of the Spanish empire in America, however, there was still limited maritime communication and trade with locations too remote to the large trade routes. In addition to dispatch ships (*avisos*), ships sailing under special permission of the crown (*registros*) occasionally supplied ports that were too remote relative to the large trade routes. However, this was never done at a sufficiently large scale (Walker, 1979) and increased the reliance on contraband trade which was sizeable (Christelow, 1942). While as a rule, there were no restrictions on inter-regional trade (Elliott, 2006, p. 111), there were instances where inter-regional trade was discouraged.⁵

Mercantilist restrictions and high trade costs ensured that trade was limited to non-competing goods with a high value-to-weight ratio. Important exports from the Americas to Spain during the period beyond precious metals were hides, tallow, sugar, indigo, and cochineal (Rahn Phillips, 1990).⁶ While a likely consequence of Spanish mercantilist policies was the underdevelopment of peripheral areas in America (Fisher, 1997, p. 73), the measures did facilitate the naval defense of convoys and limited imports to the Americas. As a result, the policies limited the flow of bullion beyond the Iberian Peninsula and kept the terms of trade in Spain's favor. It also facilitated the management of risk in a context where long shipping times and costly communication made it difficult to predict demand (Baskes, 2013). As a result therefore, in addition to remittances directly controlled by the crown, private remittances to Spain were substantial (Cuenca-Esteban, 2008).

Reforming transatlantic trade. Beginning in the 18th century, Spanish policymakers were induced by geopolitical considerations, originating mainly in Europe, to overhaul the external trading system (Elliott, 2006). In the immediate aftermath of Spain's defeat in the Seven Years' War, a special *junta* was appointed under Charles III to "review ways to address the backwardness of Spain's commerce with its colonies and foreign nations" (Stein and Stein, 2003). Drawing on ideas for reforming the system of government in America that had been circulating for a long time, the *junta* proposed the abolition of the Cadiz monopoly as well as the fleet system. Further, it proposed opening 14 ports on the Iberian Peninsula as well as 35 ports in the Americas (Fisher, 1997).⁷ Several ports in the Caribbean were opened already in 1765 (see Table 3). Further, reform was slowed by the Esquilache riots in 1766, but the liberalization proceeded and culminated in the decree of free trade in 1778, which opened

⁵For example, there were policies in place to limit trade between the Viceroyalties of Peru and New Spain to reduce the demand for the goods of the Manilla Galleon in Peru. Another example is the erection of a customs barrier in Córdoba (Argentina) in 1618 (Scobie, 1971, p. 53)

⁶The slave trade was subject to different rules. Trade of slaves was allowed for British ships from early to the mid 18th century as a result of the treaty of Utrecht, the *asiento* (Walker, 1979).

⁷The ports that were opened on the Iberian peninsula in this period was Malaga, Almería, Cartagena, Alicante, Tortosa, Barcelona, Santander, Gijón, La Coruña, Palma de Mallorca, Santa Cruz de Tenerife. While the reform is believed to have a role in promoting the rise of the Barcelona textile industry, in the early 19th century, around 80 percent of Spanish trade with the Americas still went through the port of Cádiz (Fisher, 1997).

several of the remaining ports.⁸ In the 1780s, the remaining important ports followed. Spanish communication with the Americas was disrupted during the Napoleonic wars (O'Rourke, 2006). Out of necessity, trade with neutral nations was therefore allowed. This marked the end of Spain's ability to enforce protected trade with the colonies. By the beginning of the 19th century, Spanish America enjoyed *de facto* although not *de jure* unrestricted trade with foreigners (Fisher, 1998). As a result, direct trade with Britain, not mediated through Spain, grew in importance (Prados de la Escosura and Casares, 1983). Independence was mostly followed by high tariffs, mainly driven by the revenue needs of post-independence governments (Coatsworth and Williamson, 2004).

What motivated the reform? The historical literature emphasizes the role of European interstate competition and the resulting increased need for a modernized imperial defense as being a key motivation. The drive to reform the Spanish commercial system can therefore be understood as being motivated by European interstate competition in the 18th century (Kuethe and Andrien, 2014). Highlighted in the historical literature as an important impetus for the reform was the "humiliating" capture of Havana and Manila by the British during the Seven Years' war. This opened a window of opportunity for reform-minded policymakers in Spain who now could justify reforming the commercial system with concerns about the territorial integrity of the empire in what has been described in the historical literature as a "defensive modernization" (Stein and Stein, 2003). Furthermore, the commercial expansion of Havana during the British occupation showcased the economic potential of the Spanish colonies. The reform was therefore implemented rapidly after the Seven Years' War (Fisher, 1997). As a result, the timing of the reform is mainly driven by intensified interstate competition in Europe, rather than economic development in the Americas directly. Moreover, the reform was implemented from above, and no significant ports in which the policies were applied were excluded. This is also apparent from the fact that the policies were resisted by powerful interests in the Spanish Empire (Baskes, 2013). Finally, the decision of which ports to open was unlikely to be driven by a given port's commercial potential. This is best illustrated by considering the case of New Spain. As the most important colony of the Spanish empire in America, it was believed New Spain would have diverted too much trade away from other regions (Fisher, 1997). Also avoiding confrontation with merchants in New Spain whose resources were a key source of revenue for the crown explains this hesitancy. As a result, New Spain was not subject to the reform until the late 1780s.

"Free trade" and economic development. It is generally agreed upon that the reform

⁸This was with the exception of Venezuela (Caracas), where it was believed the Caracas companies tobacco monopoly was worth protecting, and New Spain. Even so, especially Veracruz was affected by the changes before the late 1780s due to the abolition of the convoy system and the increased prevalence of register ships.

increased trade. This was recognized by contemporaries as well as in the historical literature.⁹ However, the magnitudes are contested in the economic history literature (Cuenca-Esteban, 2008). Colonial imports to Spain increased tenfold and exports from Spain to the colonies fourfold according to Fisher (1985). More modest estimates are found in Cuenca-Esteban (2008), these estimates also suggest large effects (see Figure 2). While the reform stimulated trade, the terms of trade in many ports presumably remained depressed (Francis, 2017). Fisher (1993) provides data on the composition of Spanish imports from Spanish America between 1782 and 1796 for the ports of Cadiz and Barcelona (which accounted for around 88 percent of imports from Spanish America). Precious metals still accounted for 56.4 percent of imports through this period. The other commodities were typically high-value agricultural commodities as can be seen in Figure 3 (Fisher, 1993) (tobacco 13.6, cacao 7.8, sugar 5.5, indigo 5.2, cochineal 4.2, hides 3.4 and cotton 0.4 percent). Cadiz remained the dominant port for trade with Spanish America between 1778 and 1796 (76.4 percent of total exports and 84.2 percent of imports).¹⁰

Some accounts highlight that the lower trade costs induced by the reform promoted agricultural development. "...for the first time, the metropolis succeeded in unleashing the agricultural potential of its American possessions whilst also promoting the continued expansion of mining production. The relationship between this economic growth and the liberalization of trade is abundantly clear", (Fisher, 1997, p. 197). Moreover, lower trade costs induced by unrestricted sailing potentially allowed for specialization in a wider range of commodities, such as more perishable goods. However, bullion remained an important export commodity (Fisher, 1997, p. 38). Moreover, it has been argued that the population and economies of previously stagnant peripheral colonies in Spanish America grew rapidly as a result of the reform (Mahoney, 2010). In summary, the historical literature suggests the restrictions imposed on trade in goods with the Americas stunted economic development, and efforts induced by European interstate competition to relax these marked the beginning of a process that would have large effects on trade and shape economic development in the second half of the 18th century.

3 Data

To quantitatively assess the impact of the reform, I construct a novel dataset containing geographical, demographic, and economic data of the Spanish Empire in the 18th and 19th

⁹Floridablanca (minister under Charles III) wrote about a fortunate revolution (*feliz revolución*) when referring to Spanish export growth after 1778. When referring to Veracruz, a recent immigrant described that the city went from "gloomy and ugly" to "elegant and growing" (Stein and Stein, 2003).

¹⁰The remaining important ports were Barcelona (9.6 and 3.8 percent), Malaga (4.8 and 1.3 percent), Santander (3.3 and 2.6 percent), and La Coruña (3 and 6.8 percent) (Fisher, 1993, p.20 and p.25).

centuries.¹¹ The main dataset covers the 100 year-period 1710-1810, roughly corresponding to the Spanish Empire under the Bourbon dynasty. I restrict the sample to locations that were claimed by Spain throughout the period.¹² Summary statistics of the main variables can be found in Table 1 and Table 2.

Population. As a starting point, I use city-level population data from [Buringh \(2013\)](#). Following [Bairoch \(1988\)](#) they apply a threshold rule and collect data on cities with a population exceeding 5,000 inhabitants in 1850 or 20,000 inhabitants in 2000. I restrict the sample to cities with data recorded for 1750, the last measurement before the reform, which constitutes 297 cities. Following [Arroyo Abad and Zanden \(2016\)](#), I supplement and expand this data source by digitizing population data from the historical literature. Details on the sources and approach are provided in the Appendix. I further supplement the dataset territorial gazetteer of around 15,000 places that existed in the Spanish Empire during the 18th and early 19th-century ([Stangl, 2019b](#)). The dataset is based on official records as well as various secondary sources.¹³ It contains the founding, legal status, position in the ecclesiastical hierarchy, as well as the longitude and latitude of each settlement. In the main analysis, I restrict the sample to places with the status of city, town, or village to capture the location of population centers.¹⁴ Altogether, the final dataset contains 2,125 places. Henceforth I refer to these as settlements. Data on pre-colonial population density is from [Denevan \(1992\)](#), which combine the most recent available geographical, anthropological, and archaeological findings ([Maloney and Valencia, 2016](#)).¹⁵ For New Spain and Peru, more detailed data is available for the colonial period. For these locations, I digitize data on population and tributary counts from [Gerhard \(1993a,b,c\)](#) and [Cook \(1981\)](#). Finally, I include data on contemporary population density from the Gridded Population of the World, which

¹¹The contemporary countries partly or entirely contained in the sample are Argentina, Brazil, Chile, Bolivia, Peru, Uruguay, Ecuador, Colombia, Paraguay, Venezuela, Panama, El Salvador, Honduras, Costa Rica, Guatemala, Mexico, Nicaragua, Cuba, the United States, and the Dominican Republic.

¹²This mainly excludes parts of what today are Brazil, Louisiana, and Florida. These locations had limited trade with Spain throughout the period.

¹³"Sources include archival material like census tables, mission reports, visitations of dioceses and provinces, but also more ephemeral documents like petitions of some city council which was mostly not written for giving geographic information but may touch one specific detail or incidentally exposes some relevant information. Non-archival contemporary sources include mostly highly systematic sources for information like so-called "Foreigner Guides" (printed calendar-manuals which included also lists of office holders of many parts of the Empire), maps, or geographical descriptions both printed and manuscripts." ([Stangl, 2018](#)).

¹⁴This avoids common pitfalls associated with using population thresholds for defining a settlement. The status of city was the highest legal status afforded a population center in Spanish America and was typically granted by the crown. Below the city in the hierarchy was the town (*villa*). In some cases, settlements were abandoned (such as Buenos Aires) or moved (such as Guatemala). In these cases, the date of founding is the founding of the first city in both cases. The location of the place is determined by the functional center. For example, a place served as a marketplace, the dataset includes the location of the marketplace. A place with a primarily religious function records the location of the church and so on.

¹⁵The data used in this paper have been made available by [Bruhn and Gallego \(2011\)](#) and [Maloney and Valencia \(2016\)](#).

is distributed by the (CIESIN) at Columbia University.

Sailing and trade. To estimate sailing speeds, I combine information on maritime logbooks with data on wind patterns. I use logbooks from the CLIWOC database (García-Herrera et al., 2005). The data was originally compiled for studying historical oceanic climate conditions and contains around 280,000 logbook entries for Spanish, Dutch, French, English, and Swedish ships between 1750 and 1850. The logbook entries contain the daily longitude and latitude, wind speed and direction as well as several voyage-level characteristics such as the ship name, origin, destination, captain name, and ship type.¹⁶ Information on the average speed and direction of the sea-surface winds by $0.5^\circ \times 0.5^\circ$ cells for each week between 2011 and 2017 is from the US National Oceanic and Atmospheric Administration (NOAA).¹⁷

I digitized data on trade flows come from two separate sources. First, data on trade between Spain and America at the port-level is primarily from Fisher (1985) and Fisher (1993). These data have been compiled from primary sources, mainly from the General Archive of the Indies in Seville. It contains data on the share of Spanish foreign exports to the 19 largest American ports as well as the total value (measured in *reales de vellón* in constant prices). Moreover, it contains data on the composition of trade and the number of ships arriving at Cadiz from a range of American ports. I also digitize data on prices in Spain (Castille) using data from Hamilton (1947) and use price data from GPIH.¹⁸ Data on the slave trade is from Behrendt et al. (1999).

Geography and infrastructure. I use data on agricultural suitability measures from FAO's Global Agro-Ecological Zones under rain-fed, low-input agriculture for six important staple and export crops. The staple food in Mexico and the Andean countries was maize while wheat was the important staple in Chile and Argentina. Important export crops were cotton, tobacco, sugarcane, and cacao which constituted around 27.3 of total exports from Spanish America to Spain in this period (Fisher, 1993). I supplement these data with the maximum attainable caloric yield using data from Galor and Özak (2015, 2016). The potential caloric yield is chosen because the relative caloric content is economically important in a pre-industrial context. Furthermore, it isolates features of the natural environment affecting attainable yields, but that are exogenous to human intervention. Information on urban nominal wages (measured in grams of silver) is from Arroyo Abad, Davies and van Zanden (2012). Furthermore, I calculate the terrain ruggedness index, average slope, and elevation. Information on climatic variation is from Hijmans et al. (2005).

I collect data on the location and trading status of each port is from the decree *Reglamento y aranceles reales para el comercio libre de España a Indias de 12. de octubre de 1778* (Ramírez Bibiano

¹⁶In the case of Spanish ships these are *paquebote*, *fregata*, and *navio*.

¹⁷For cells covering land, the wind speed is set to zero to prevent routes from crossing land.

¹⁸Available at <https://gpih.ucdavis.edu/>.

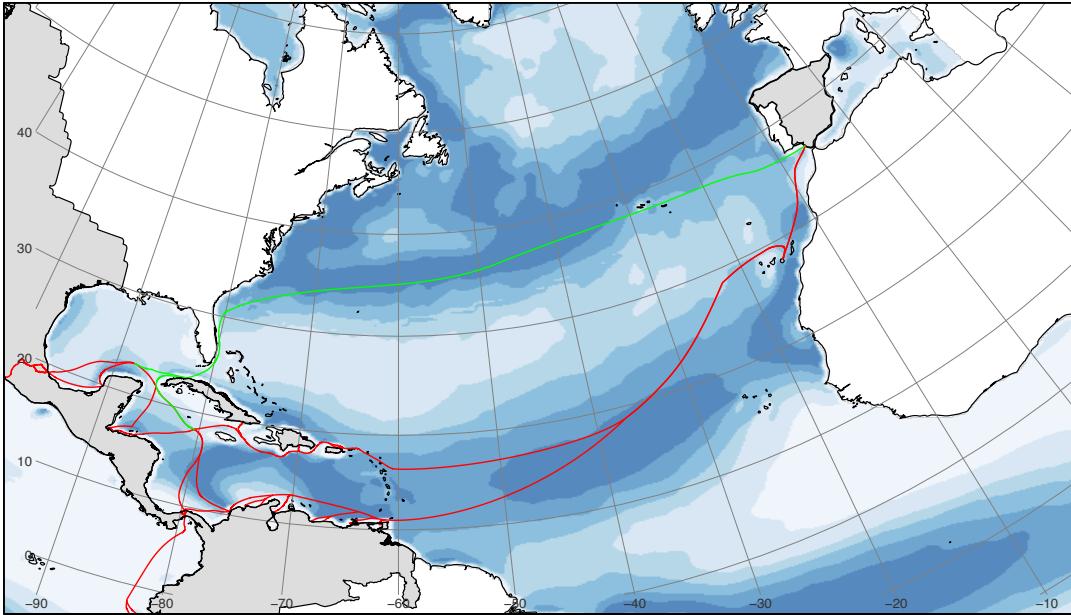

Figure 6: The figure depicts the cost surface of maritime travel between 1750 and 1850. The map plots the average cost for each $1^\circ \times 1^\circ$ grid-cell where darker colors indicate higher predicted sailing speed. Grey areas denote territory claimed by the Spanish Empire in 1790. The cost surface is calculated from predicting sailing speeds from wind direction and speed. The estimated relationship is extrapolated on gridded data of wind direction and wind speeds covering the world oceans. The red and green lines denote historical trade routes. Red denotes the westward journey while green denotes the eastward journey. Source: NOAA and CLIWOC.

and [Ortíz de la Tabla, 1978](#)), as well as [Fisher \(1997\)](#). I validate the data with various other secondary sources. The list of ports can be found in Table 3. Further, I include the location of the principal mining centers (*Reales de Minas*) in the 18th century from [Fisher \(1997\)](#).¹⁹ Together, mining, cotton, tobacco, sugarcane, and cacao exports make up around 83.7 of all exports from Spanish America to Spain in the period. Viceregal and *audiencia* borders are from [Stangl \(2019b\)](#).²⁰ Finally, I use mail routes to proxy for the location of roads ([Stangl, 2019a](#)). I include data on potential vegetation to control for various geographical fundamentals as well as using landcover to calculate travel speeds ([Ramankutty and Foley, 1999](#)). I include data on the location of rivers and lakes using data from Natural Earth which allows me to control for time-varying effects of distance to waterways and fresh-water access.

4 Shipping Times and Trade Costs

In this section, I compute trade costs between locations in the Spanish Empire in the 18th century. While trade costs in this context are a function of a range of factors, I exploit that

¹⁹I identify in total 78 locations across the Spanish Empire mined for silver, mercury, gold, salt, emeralds, copper, platinum, or iron.

²⁰Viceroyalties and *audiencias* were basic territorial units of Spanish colonial rule. The viceroyalties were subdivided into *audiencias*, which were further subdivided into governorships and provinces ([Mahoney, 2010](#)).

trade costs are well known to depend on distance in historical settings (Flückiger et al., 2019; Barjamovic et al., 2019). I leverage this by constructing a directed graph, where nodes denote localities and edges the shipping times to all adjacent nodes.

4.1 Estimating Trade Costs

Maritime transportation. I estimate the sailing speed by using information from maritime logbooks in the 18th and early 19th centuries. From each logbook entry, I extract information on recorded wind speed, wind direction, and travel direction. I follow Kelly and Ó Gráda (2019) and remove observations for which either the inferred speed is implausibly high (above 10 knots), or are located in coastal areas. Figure 4 panel (a) shows the distribution of recorded wind directions and panel (b) travel speeds. The figure shows that the average sailing speed was around 5 knots and that most sailings took place in the direction of the wind or at 90 degrees where sails work most efficiently (Pascali, 2017; Kelly and Ó Gráda, 2019). To estimate the relationship between wind direction, wind speed, and sailing speed, I consider the following model,

$$S_i = e^{f(\theta_i, ws_i) + \epsilon_i}, \quad (1)$$

where ws_i measures the wind speed in grid-cell i , θ_i measures the deviation of the angle between the wind direction and direction of travel, S_i denotes the sailing speed, and ϵ_i is an error term. Given a large number of features, Equation 1 is estimated using an elastic net where tuning parameters are chosen optimally using 10-fold cross-validation (Zou and Hastie, 2005). The full sample ($N = 37,141$) is then split into a training sample (80 percent of the sample) and a validation sample. I fit the model on a training sample and then test its performance in a validation sample. The model predicts sailing speed accurately (with a mean absolute error of 1.48 in the preferred model). Next, I average weekly high-resolution data on wind speed and wind direction from NOAA over the period 2011-2017. For every node in the graph, I then calculate the predicted sailing time between all adjacent nodes using \hat{S}_i .²¹

Overland transportation. Mules were the most common means of bulk transportation for most of the colonial period and up to the second half of the 19th century. For the case of New Spain, there were typically groups of 50 pack animals (*recuas*) with one individual (*arriero*) per five animals, each carrying a load of around 113 kilograms (Hassig, 1993). I calculate the costs faced by shipping with pack animals using geographical features, drawing on least-cost analysis tools from archaeology (White, 2015). The pace will depend on whether travel occurs

²¹The graph is weighted again to account for the fact that the distance between the nodes of the graph varies due to their relative position as well as curvature of the earth.

on road, the slope of the terrain, the elevation, and the land cover. The predicted speed of travel between node i and j is given by W_{ij} and based on the Tobler function (Tobler, 1993),

$$W_{ij} = \kappa_i \times 6.096 \times e^{-3.5|sl_{ij}| + 0.05| -\gamma elev_i |} \quad (2)$$

where sl_{ij} measures the slope between cells i and j , κ_i is a coefficient determined by the landcover in cell i , and $elev_i$ denotes the elevation in meters ($\gamma = -0.0001072$).²² As a consequence, for travel on flat terrain at sea level the predicted speed is around 5 kilometers per hour. To adjust for differences in landcover, I rely on coefficients from Weiss et al. (2018). Five terrain types have a natural mapping between historical land cover data and the terrain coefficients.²³ Lastly, I rely on data on official routes for mail in the Spanish Empire during the Bourbon period to proxy the location of roads. Travel on a road is affected by the slope and elevation, but not the landcover. The walking speed is then used to construct the time required to travel between all nodes.²⁴

Least-cost path problem. Once the duration of passing between all adjacent cells is known, I calculate the bilateral travel time between all cells by searching for the cost-minimizing route of getting from a cell i to any other cell j along the graph. Since there will be many alternative routes to ship a good between localities i and j , I assume the time-minimizing routes according to the Dijkstra algorithm (Dijkstra, 1959) are chosen (see Figure 5 for an example). Beyond sailing speed, the turnaround time in port shapes the total shipping time of a route. Since it is not clear whether turnaround times improved over time (Rönnbäck, 2012), I assume these are constant at zero as a starting point. Moreover, I model Europe as a point-like country centered on Cadiz containing the population mass of Spain, the United Kingdom, and France in 1700. I choose Cadiz because the majority of legal trade with Europe was channeled through this port throughout the period.²⁵ This approach results in a $R \times R$ dimensional matrix of bilateral travel times between all the locations, $\mathbf{T}_t[T_{ij} \geq 0]$, where R denotes either the number of cities or grid-cells. I calculate one matrix for every decade, accounting for which ports were open to direct trade with Europe in a given decade, and I

²²While Equation 3 models walking speed, the use of pack-animals will not have affected the speed much since these were typically accompanied by humans on foot (Verhagen, Joyce and Groenhuijzen, 2019).

²³These are tropical forests, temperate forests, desert, savanna, and shrubland. The terrain factors are 0.324 in a tropical forest, 0.648 in a temperate forest, 0.97 in a savanna, 0.6 in shrubland, and 0.6 in deserts. Inland water can be crossed at half the speed (Herzog, 2014).

²⁴Özak (2018) develops a *Human Mobility Index* to calculate pre-modern travel times. This measure is not appropriate in this context because I use context-specific features such as the location of paths and maritime technology available during the period.

²⁵Furthermore, the comparative advantage of other European countries was similar to that of Spain where manufactured goods were traded with primary commodities. In the case of Britain, the share of direct trade with Latin America became the most dominant towards the end of the colonial period, starting in the early 18th century (Prados de la Escosura and Casares, 1983).

refer to \mathbf{T}_t as the travel time matrix in decade t .²⁶

Shipping time elasticity. Finally, I calculate the elasticity of the value of trade with respect to shipping time. I estimate the following model,

$$\ln X_{jt} = \alpha_r + \gamma_t + \beta \ln T_j + \epsilon_{jt}, \quad (3)$$

where X_{jt} is the value of exports from Spain to port j in year t . α_r accounts for regional heterogeneity that is unlikely to be driven by shipping time, for example route-specific factors such as risk caused by weather variability or piracy.²⁷ Finally, γ_t accounts for year-specific factors affecting trade during the period, such as interstate conflict. β denotes the elasticity of trade with respect to shipping time. A challenge is that missing data on bilateral trade between American ports prevents me from fully accounting for multilateral resistance terms, which arise in a large class of trade models (Anderson and Wincoop, 2003). However, since trade in this context was a closed system, trade with third countries is less of a concern in the current context.

4.2 Assessing the Shipping Times

I validate the estimated shipping times in different ways. As a first pass, I find a good correspondence between predicted trade routes and the location of known historical trade routes.²⁸ An example is illustrated in Figure 6. Next, I quantitatively assess the quality of the estimates in three ways. First, I compare the results to measures sailing times according to a database of bilateral sailing times.²⁹ For each port, I calculate the sailing time from Cadiz to all the ports in the dataset for which the website records information. The average speed of 5 knots is used, the average speed of Spanish freight ships in 1750 (Kelly and Ó Gráda, 2019). For shipping on land, I compare the calculated shipping times with walking times using the Human Mobility Index (Özak, 2018) as well as google maps. Finally, I consider the correlation between predicted travel time and the duration of mail dispatches between major ports in Spanish America (Baskes, 2013). Figure 7 shows that these alternative shipping time measures are correlated with the measure developed in this paper. Furthermore, I assess the correlation between historical and contemporary wind patterns. There is a strong

²⁶In the baseline case there are 298 cities and 5,015 grid-cells (including Europe).

²⁷The decline in piracy and privateering has been highlighted as an important source of productivity growth in shipping in the first half of the 18th-century (North, 1968). These factors had become less important towards the end of the 18th century (Hillmann and Gathmann, 2011). While risk undoubtedly played an important role, it presumably affected the timing of departures more than choices between different routes.

²⁸For example, Pacific and Atlantic ports are connected by the Panama isthmus, Mexico City is connected to maritime trade through Veracruz and Acapulco, and Potosí and Arica with Callao.

²⁹A database of bilateral sailing times between major ports around the world. Data available at seadistances.org.

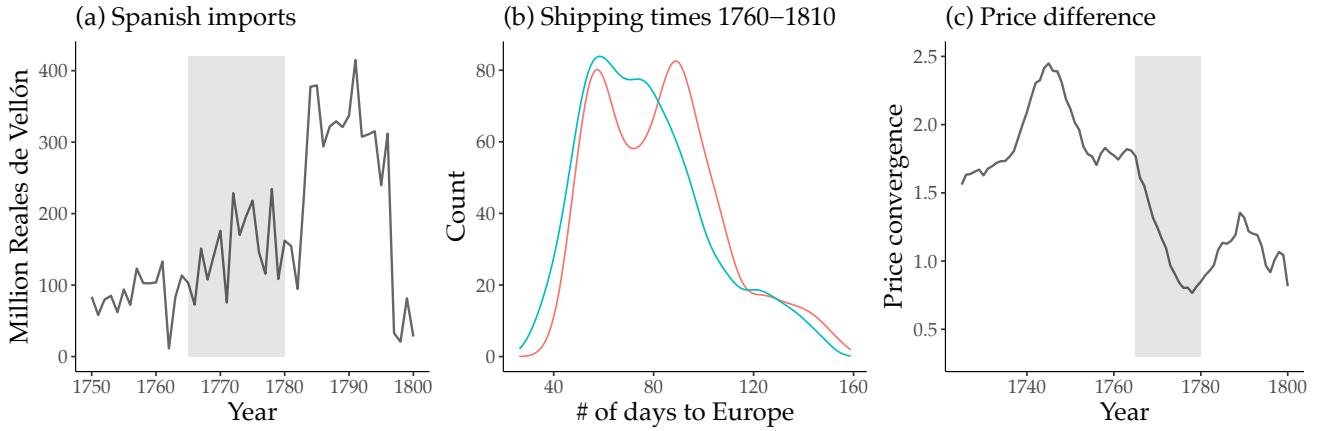

Figure 10: Panel (a) depicts the value of private non-bullion imports to Spain from American ports between 1750 and 1800 at constant prices. The shaded area denotes the main reform period. Data for 1780 is missing in the original data source (imputed with the average for the whole period). Data are from [Cuenca-Esteban \(2008\)](#). Panel (b) depicts the number of days' travel from a grid-cell to Europe in 1760 (red) and 1810 (green) for the grid cells in the sample. Panel (c) depicts the difference in the average log price for commodities (salt, sugar, cinnamon) in Spain (Castille) and cities in Spanish America (Buenos Aires, Potosí, Lima, Bogotá, Santiago de Chile, Mexico City).

correlation between wind speed and direction in these two datasets. A remaining concern is that changes in maritime technology changed the relationship between distance and trade costs over the period. However, improvements in maritime technology were unlikely to be the most important determinant of productivity gains in shipping before the 19th-century ([North, 1968](#); [Harley, 1988](#); [Menard, 1991](#)).³⁰ Since maritime productivity gains were limited, potential measurement error in travel times is unlikely to be changing over time. Taken together, the exercises show that the determinants of trade costs emphasized in the estimation were important in the context.

5 Reduced-Form Evidence

In this section, I use the calculated changes in trade costs to examine the effects of trade on the location of economic activity and economic growth. I document four main results.

5.1 Results

Fact 1: *The reform promoted market integration.* To assess the effect of the reform on market integration, I first consider the evolution of trade during the reform period. The value of Spanish non-bullion imports from the Americas is shown in Figure 10a. While there is no secular increase in imports before 1765, there is a positive trend coinciding with the onset

³⁰This view has recently been challenged by ([Kelly and Ó Gráda, 2019](#)). However, they show that Spanish sailing speeds remained stagnant throughout the study period.

of the reform. After the largest wave of port openings in 1778, the value increased nearly fourfold.³¹ Exports from Spain exhibit similar patterns as is depicted in Figure 2c. The timing of the increase is consistent with the reform increasing trade, but could be driven by other time-variant determinants of economic activity.

How was the increase in imports distributed across ports with different treatment intensities? Let ΔT_i denote the decline in shipping time induced by the reform for location i measured in days ($\Delta T_i = T_{i1760} - T_{i1810}$). Figure 9 displays the number of ships and the total value of imports to Spain originating from treated ($\Delta T_i > 0$) and untreated ($\Delta T_i = 0$) ports using data from (Fisher, 1985). Although there is an increase in the number of ships and the value of imports originating from both treated and non-treated ports, the increase is substantially larger for the treated ports. Before the reform, the number of ships arriving in the treated ports was limited.³² The effects are unlikely to be driven by contraband for three reasons. First, smuggling is less likely to be an issue when considering imports to Cadiz which was the port most closely monitored by the crown (Fisher, 1985, p. 32). Second, estimates of the extent of smuggling are too small to account for the large increase in trade. Lastly, the increase not only in the value of trade but also in the number of ships is not consistent with smuggling explaining the increased trade volume.

What drove this rapid increase in trade? It remains possible that the growth is partly driven by increases in income or productivity that happened to coincide with the reform in treated ports. To explore this further, Figure 10b presents the change in shipping time between 1760 and 1810 induced by the opening of ports for direct trade with Europe. The red curve denotes the shipping times in 1760, while the green curve the distribution of shipping times in 1810. The figure shows a leftward shift in the distribution of shipping times. The reduction in shipping time ranges from 0 to 27 days and is 6 days lower on average. Since the pre-reform average is around 83 days, the reduction is economically significant.³³ Table 4 shows the relationship between shipping times and the value of exports from Spain between 1797 and 1820. Across all the specifications, there is a negative relationship between the shipping time and the value of trade. As a result, the reductions in shipping times are consistent with improved market integration.

To further corroborate that improved market integration was a key driver for the trade growth, I leverage information on price differentials for various commodities (salt, sugar, cinnamon) in Spain and various cities in Spanish America. Figure 10c shows the average log price differential calculated in five-year periods over the 18th century. For these commodities, there is a reduction in the price differential also coinciding with the reform. A t-test for

³¹The slightly delayed response is explained by the Spanish involvement in the American Revolutionary War which disrupted trade.

³²See e.g. Walker, 1979, p. 230, for the number of register ships arriving in Spanish America 1701-1740.

³³Figure 8 shows the spatial distribution of the changes in trade costs.

the average price differentials being different before and after 1765 rejects the equality at conventional levels of significance. In sum, the timing of the increase in trade, the disproportional increase in imports originating from treated ports, the reduction in trade costs, and price convergence provide evidence that the reform promoted market integration.

Fact 2: *The reform induced urban growth.* Next, I explore how the change in shipping time to Europe affected urban population growth. Consider the following model,

$$\ln L_{it} - \ln L_{it'} = \gamma_v + \beta \Delta T_i + \phi x_{it} + \epsilon_{it}, \quad (4)$$

where L_{it} is the population in city i at time t , ΔT_i measures the decline in the number of days of shipping from the city to Europe, x_{it} is a vector controlling for geography, climatic characteristics, disease environment, and historical resource availability, and ϵ_{it} is an error term potentially spatially correlated across nearby locations. To account for mean reversion and differences in population growth that is depending on city size ([Duranton and Puga, 2014](#)), I also control for the initial population in some of the specifications.³⁴ In the baseline specification, standard errors are clustered at the level of the closest port.³⁵ The coefficient β captures the effect of a one standard deviation change in ΔT_i on the population growth in city i . The key identification assumption is that *changes* in population growth in locations with different *changes* in trade costs would have been the same in the absence of the reform. Furthermore, proxying 18th and 19th-century geographical characteristics with contemporary data sources requires further assumptions. Throughout, I assume that the variables have remained fixed or changed with the same factor across different locations. While measurement error in the outcome variable remains a possibility, classical measurement error does not lead to bias in the estimate of β . Since non-classical measurement error can potentially vary across time and location, I include region fixed-effects denoted by γ_v .

Table 5 shows the relationship between changes in shipping times and city growth. Panel (a) presents the effect of changes in shipping time on population growth between 1750 and 1800. Across a range of specifications, there is a positive relationship between changes in shipping times to Europe and population growth. Cities with larger reductions in shipping time grow faster on average. In the preferred specification in Column (4), containing both viceroyalty fixed effects in addition to the full set of controls, I find that one standard

³⁴To proxy for the disease environment, I construct an indicator variable that takes value 1 if the average elevation is below 1500m and control for distance to the coastline. There is no data on the disease environment at high geographical resolution available for Spanish America in the 18th century. However, as pointed out in [Bruhn and Gallego \(2011\)](#), [Hong \(2007\)](#) shows that the main predictors of deaths due to malaria in North American frontier forts in the 19th century are variables related to climate and elevation, which I do control for in a flexible manner.

³⁵I also account for spatial dependence in the error term by explicitly allowing for spatial correlation ([Conley, 1999](#)). The distance kernel chosen has a cutoff of 5,000km. This correction matters little for the size of the standard errors, as can be seen in the appendix.

Table 5: Shipping time and urban population growth

Dependent variable:	City population growth: $\ln L_{it} - \ln L_{it'}$

Note: The table reports OLS estimates. Shipping time is standardized. The unit of observation is a city in a certain year. **Dependent variable:** The change in the natural logarithm of the city population. **Controls:** Elevation, crop suitability, the location of active mines, distance to the coastline. **Standard errors:** Clustered at the level of the closest port. *** $p < .01$, ** $p < .05$, * $p < .1$

deviation larger reduction in the shipping time to Europe (6.5 days) leads to an around 8 percentage point increase in urban population growth ($\beta = 0.079$). The estimated coefficients range from 0.079 and 0.12. Panel (b) shows the estimates for the 1750 to 1850 period for which the estimates are nearly twice as large. Reassuringly, the estimates for 1700 to 1750 are significantly smaller and statistically insignificant.

Economic expansion, an increased military presence, and missionary activity also led to the formation of new settlements during the 18th-century (Morse, 1974). Did the changes in shipping time also induce growth on the extensive margin? To explore this, I estimate Equation 4 with the number of settlements per grid-cell as the dependent variable. Aggregating the number of settlements by the grid-cell reduces measurement error in the recorded location and makes the variable less sensitive to the grid-cell size. Table 6 shows the relationship between shipping times and the formation of new settlements. Panel (a) presents the results estimated between 1750 and 1800. The estimates are positive and significant but smaller in magnitude than the effect on city growth. One standard deviation higher reduction in

the shipping time increases the number of settlements in a grid-cell by 0.044 in the baseline specification. Again, it is reassuring that the change between 1700 and 1750 is unrelated to the change in shipping time which is consistent with the identification assumption. Taken together, the estimates are consistent with cheaper access to traded goods inducing urban growth.

Fact 3: *The reform had a smaller effect on urban growth in larger markets.* The reform affected cities that differed substantially in terms of population size. In smaller cities, the local market is potentially less important relative to markets in other cities and as a result, a change in external trade cost can have a larger impact in smaller cities ([Redding and Sturm, 2008](#)). To explore this, I interact the initial population size with the change in trade costs using the baseline specification in Equation 4. The results are presented in Table 7. Across all specifications, the interaction between changes in shipping time and the pre-reform city population is negative. While there is a positive effect of lower shipping time for the cities with the average population size, a one standard deviation increase in the population size in 1750, reduced the marginal impact of a change in the shipping time to zero. I find no effect of the interaction with growth on the extensive margin. To further explore the role of the own market size in mediating the effect, I split the sample into a colonial center, semiperiphery, and periphery following [Mahoney \(2010\)](#).³⁶ The core and semiperiphery are by far the largest internal markets. The results are reported in Table 8 and show that the average effect is driven by cities in the periphery, further suggesting that the effect is mediated by the pre-reform market size.

An alternative interpretation is that larger cities are closer to their urban carrying capacity, which in turn limits how much the population size adjusts to lower trade costs. However, in Columns (2)-(3) I control for different measures of the local resource availability. Since the negative interaction remains across these specifications the findings are not consistent with this mechanism. Measurement error in a city's population size is a concern when population size enters as an explanatory variable. To address this, I use a more stringent fixed effect specification in Column (4) which also controls for unobserved time-variant heterogeneity at the *audiencia* level. Also in this specification, the estimated coefficient is negative and significant. Furthermore, it is reassuring that there is no effect on population growth, both for the interaction and the un-interacted terms, for the period 1700 to 1750. Finally, Figure 11 depicts the result from interacting a range of additional variables with the decline in shipping times. As can be seen in this Figure, the interaction with the initial population size stands out in magnitude. In sum, the result is therefore consistent with the pre-reform market size

³⁶The colonial core consists of Mexico, Peru, Bolivia, the colonial semiperiphery consists of Guatemala, Ecuador, Colombia, while the periphery consists of Uruguay, Argentina, Chile, Paraguay, El Salvador, Honduras, Nicaragua, Costa Rica ([Mahoney, 2010](#), p. 50)

being important in mediating the effect of the change in trade costs.

Fact 4: *There is a high degree of persistence in the pre-reform settlement pattern, but it is lower in areas more exposed to the reform.* To explore the persistence of historical settlement patterns, I estimate the elasticity of contemporary population size with respect to its pre-reform population size. I estimate the following model,

$$\ln L_{it} = \alpha_c + \beta \ln L_{it'} + \phi x_i + \epsilon_{it}, \quad (5)$$

where L_{it} denotes the population size of location i in year 2000, $L_{it'}$ denotes the population size in year 1500 or 1750, x_i is a vector of pre-determined control variables, and ϵ_{it} is an error term potentially correlated across nearby locations. Standard errors are therefore clustered at the country level in the main specifications.³⁷ To account for differences in measurement error across locations, the specifications contain country fixed-effects as captured by α_c . β is the elasticity of contemporary population size with respect to the pre-reform population size. To explore the role of the reform in affecting the persistence of historical settlement patterns, I estimate Equation 5 separately for locations that were differentially exposed to the reform. I therefore make the assumption that the locations that experienced different changes in shipping time would have had similar elasticities β in the absence of the reform, conditional on the set of controls.

Table 9 shows the results for the baseline sample of cities. In the preferred specification in Column (4), the elasticity for the full sample is 0.34. The elasticity for the above-median sample is 0.28 while it is 0.44 for the below-median sample. This pattern is mirrored using data from Denevan (1992). Figure 13 shows the relationship between pre-colonial population density and the current population for the different samples. Figure 13a shows the correlation for all regions in the study region. Consistent with Maloney and Valencia (2016), there is a strong persistence as measured by the positive relationship within-country between pre-colonial population density and population density in 2000. Figure 13b shows the relationship between the two variables for the sample of provinces that experienced low changes in shipping costs ($\Delta T < \text{Median}$). The figure shows that persistence is more pronounced for this subsample. Finally, Figure 13c shows the relationship to be weak in the subsample of provinces that experienced large changes ($\Delta T \geq \text{Median}$). Table 10 shows that the pattern is robust across several specifications. When using the data from Denevan (1992) the differences between the groups are highly statistically significant, however, for the city-level data the difference is noisier. In sum, the results from Table 10 support the interpretation that the changes in trade costs induced urban growth and attenuated the

³⁷To address concerns about spatially correlated errors, I also calculated the Conley standard errors (Conley, 1999).

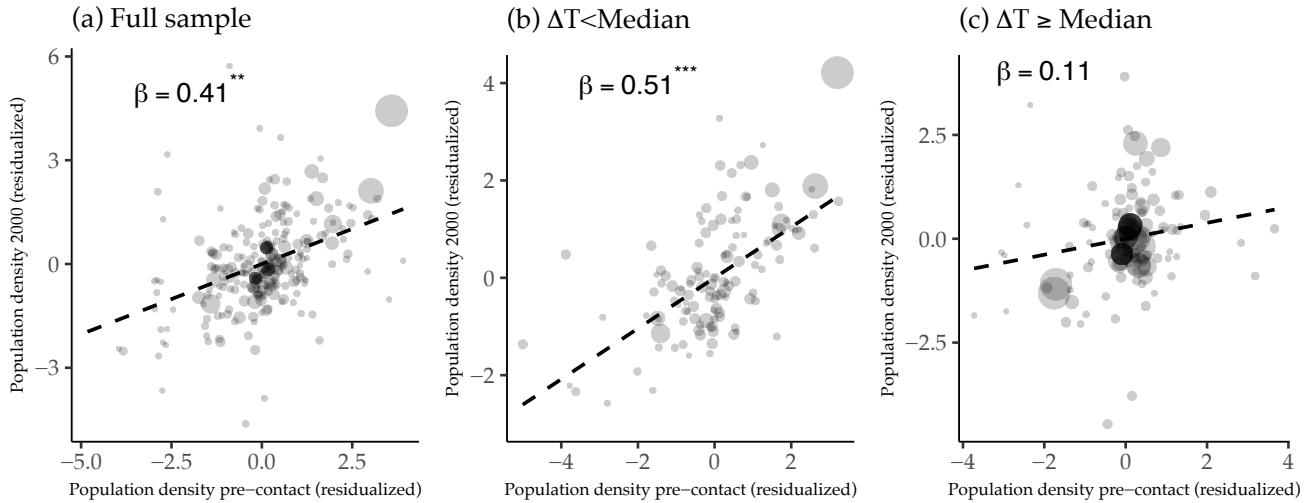

Figure 12: The figure depicts the relationship between pre-contact population density and the population density in the year 2000 at the province level. The left figure depicts the relationship for the full sample. The middle figure depicts the relationship for provinces with below-median change in the distance to Europe between 1760 and 1810. The right figure depicts the relationship for the sample above-median reduction in shipping time to Europe between 1760 and 1810. Pre-colonial population density is the number of people per square kilometer pre-contact. The dependent variable is the log of people per square km in 2000. The full sample contains 340 observations. **Geographical controls:** Altitude, ruggedness, rainfall, and inverse distance to the coast (see [Maloney and Valencia \(2016\)](#) for details). **Standard errors:** Clustered at the country-level.

persistence of pre-reform settlement patterns. While there is certainly measurement error in the data from [Denevan \(1992\)](#), it is reassuring that I find a similar elasticity using tributary counts from [Gerhard \(1993a,b,c\)](#). This can be glanced in Figure 12.

5.2 Assessing the Research Design

The identification assumption is that, in the absence of the reform, urban population growth would have happened at an equal rate across areas that, under the reform, experienced different reductions in shipping costs. To assess the plausibility of this assumption, I consider the dynamic version of Equation 4 where the change in shipping time is interacted with decade indicators. I estimate the following model

$$\ln L_{it} = \alpha_i + \tau_t + \sum_{s=1710}^{1810} \mathbb{1}[t = s] \Delta T_i \times \tau_s + \phi x_{it} + \epsilon_{it}, \quad (6)$$

where the variables are defined as in Equation 4. Figure 13 shows the estimated coefficients using the baseline specification for both population growth and the formation of settlements. The plotted coefficients give the estimated difference between differentially exposed localities in year s relative to 1760, which is the last year prior to the reform. Consistent with the identification assumption, Figure 13 shows that there is no significant difference in population

growth in areas with different exposures to the reform prior to 1750.³⁸ Table 11 summarizes several alternative specifications. This pattern can also be seen in Figure 10.

Another threat to the research design is that the effect is not driven by changes in the trading environment, but rather other events occurring in the late 18th century. Other administrative, ecclesiastical, and military reforms were conducted in Spanish America. One important reform was the separation of the Viceroyalty of *Rio de la Plata* from the Viceroyalty of Peru in the second half of the 18th century. It is possible that this induced economic growth to be reoriented towards Buenos Aires in a way that was correlated with the reduction in shipping times. However, when dropping cells in the Viceroyalty of *Rio de la Plata* or the whole of Argentina the estimated coefficients are similar. Moreover, I exploit the fact that the Viceroyalty of *Nueva Granada* with the capital in Bogota separated from the Viceroyalty of Peru already in 1717. I do not find evidence that this reform affected city growth. Next, I use viceroyalty and *audiencia* borders between 1710 and 1750 multiplied with time fixed effects which removes differences in average growth rates across locations that could experience different institutional developments.

To further assess the possibility of time-varying confounders, I consider the stability of the point estimate in Table 5 when adding the control variables. It is reassuring that the estimated effect of declining shipping times on urban growth is stable to the inclusion of these variables as can be seen in Column (2)-(4) of Table 5. Moreover, the increase in the R^2 shows that the variables explain variation in both the decline in shipping times and urban growth. A more systematic approach to sensitivity analysis is developed in [Cinelli and Hazlett \(2020\)](#). I follow this approach and calculate the robustness value (RV), which quantifies the strength any unobserved confounder would need to account for the estimated effect. I find that a robustness value of 17.64 to account for a true effect of zero, and 7.64 to account for a true effect that is statistically insignificant. In other words, if there exists a confounder that explains 17.64 of the outcome and the treatment, then controlling for this confounder would make the effect of declining shipping time zero. This is substantially larger than the effect control variables such as the initial population size. As a result, the estimated effect of the decline in shipping time is unlikely to be driven solely by an unobserved confounder not included in the regression.

Here I briefly discuss some additional robustness checks. Even though all large ports were eventually allowed to trade directly with Europe, and even though the historical literature suggests the opposite, it cannot be ruled out that the timing at which ports opened was driven by their economic potential. To mitigate this concern, I restrict the sample to only include areas far away from ports in the estimation. These were unlikely to be directly targeted by the

³⁸I conduct a formal test of the joint significance. In all specifications, the hypothesis that the pre-trend coefficients are zero cannot be rejected.

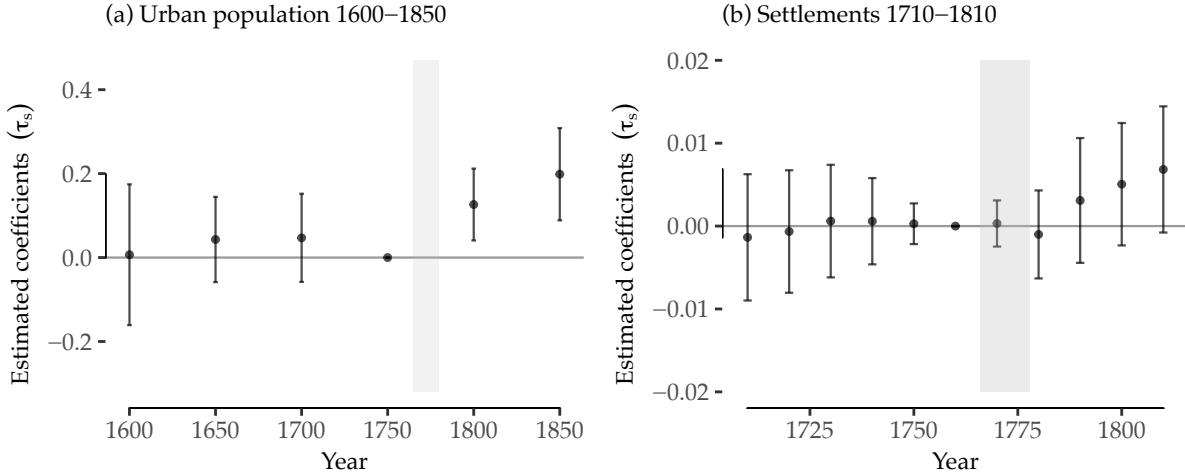

Figure 13: The figure depicts the estimated coefficients of the difference in population growth and the number of settlements according to the reduction in shipping times to Europe induced by the reform. **Dependent variable:** In panel (a) the log of city population. In panel (b) the number of settlements per grid-cell. **Observations:** In Panel (a) 297 cities for the period 1600–1850 totalling 1,782 observations. In panel (b) 5,014 $0.5^\circ \times 0.5^\circ$ grid-cells for the period 1710–1810 totalling 55,154 observations ($11 \times 5,014 = 55,154$). **Controls:** Elevation, crop suitability, the location of active mines, distance to the coastline, and terrain ruggedness. **Standard errors:** Clustered at the port-level.

reform. To account for potentially spatially correlated error terms, I calculate standard errors accounting for spatial correlation in line with [Conley \(1999\)](#). Next, I remove outliers for all the outcome variables. To further address concerns about measurement error, I re-estimate the model for cities in locations with high state capacity. Following [Acemoglu, Mosconia and Robinson \(2016\)](#), I measure state capacity by the location of post offices in 1750.³⁹ The effects on urban growth are already positive before independence. However, if trade contributed to political fragmentation of the Spanish Empire (see e.g. [Arteaga \(2016\)](#) and [Bonfatti \(2017\)](#)), then conditioning on country fixed effects might induce post-treatment bias. I address this by estimating the model with virtual country fixed effects. Finally, I explore the relationship between increased access to trade on the slave trade. Did the improved trade opportunities induce population growth through the slave trade? Using data from [Behrendt et al. \(1999\)](#), which covers around 80 percent of all voyages of the slave trade, I find little evidence of this mechanism. Most of these further results are reported in the Appendix. Taken together, these exercises provide support for the causal interpretation of the estimates. The findings provide evidence that cheaper access to traded goods and better export opportunities increased urban growth and that the size of the internal market was important in mediating the effect.

³⁹This draws on the notion of infrastructural power, or “the capacity to actually penetrate society and to implement logically political decisions” ([Mann, 1986](#), p. 170), as being an important determinant of state capacity.

6 A Model of Trade and Urban Growth

In this section, I explore potential mechanisms and long-term implications by interpreting the findings through the lens of a parsimonious dynamic spatial general equilibrium model that I calibrate to match the observed data.

6.1 Theoretical Framework

Geography. The model consists of $i = 1, \dots, R$ cities ($R = 298$ in the baseline case). Cities differ in their productivity A_i , their hinterland's availability of arable land H_i , and in their connectedness to other cities in terms of trade and migration. A_i determines the city's productivity in traded goods production and H_i determines the urban carrying capacity (Bairoch, 1988; Hassig, 1993; Duranton, 1999). Inhabitants in each city can trade with and migrate to all other cities subject to a cost. Let τ_{ij} and m_{ij} denote the trade and migration cost between locations i and j respectively. Europe enters the model as a point-like country centered on Cadiz and contains the population mass of Western Europe for each decade. Each period in the model corresponds to the timing in the main dataset. One period therefore corresponds to 50 years.

Preferences. The city's inhabitants have a Cobb-Douglas utility function defined over a composite of location-specific traded goods and a non-traded good (food).⁴⁰ This captures that long-distance trade during the 18th century was limited to non-competing goods (Findlay and O'Rourke, 2007). The welfare derived from consumption for an individual living in location i is therefore given by,

$$V_i = w_i / P_i^\mu r_i^{1-\mu}, \quad (7)$$

where μ is the share of expenditure of the traded good, P_i is the price index for the traded goods, w_i is the nominal wage, and r_i is the price of land. Consistent with evidence that real wages responded to long-run changes in market conditions in the context of colonial Mexico and Peru (Allen, Murphy and Schneider, 2012), I assume that labor markets are competitive over the 50 year period. Each household supplies labor inelastically.

Production. Agriculture was the largest sector of the economy (Arroyo Abad and Zanden, 2016), and the availability of arable land and high trade costs played an important role in limiting urban growth in pre-industrial cities.⁴¹ To capture this, I assume there are two sectors in each city, a sector producing the location-specific traded good and an agricultural sector

⁴⁰I abstract from differences in agricultural intensification in the hinterland depending on the distance to the city which arises in a von Thünen model.

⁴¹Mining only employed around 0.04 percent of the population at its peak in the late 18th century (Fisher, 1997, p. 64) (75,000 out of 17 million).

producing food that is non-traded. Since production takes place under perfect competition, the price of the location-specific traded good in location i is given by $p_i = w_i / A_i$. The agricultural sector features constant returns to scale where one unit of land produces one unit of food. Since the land market is competitive and supply exogenous, the land price is given by $r_i = (1 - \mu)Y_i / H_i$. Income from land is allocated lump-sum to all inhabitants of the location.

Trade and migration. Trade is subject to iceberg transportation costs. As a result, the price faced by an individual in city j for a good produced in i is given by $p_{ij} = \tau_{ij}p_i$. The model then gives rise to a gravity equation for bilateral trade flows between cities. Using the demand function for the traded goods gives the value of trade from location j to location i by

$$X_{ji} = q_{ji}p_{ji} = p_{ji}^{1-\sigma}\mu Y_i P_i^{\sigma-1}. \quad (8)$$

Legal restrictions on labor mobility and coercive labor institutions had lost importance by the end of the 18th-century ([Arroyo Abad and Maurer, 2019](#)) and pre-industrial city growth was mainly driven by migration ([Cook, 1981; Jedwab, Christiaensen and Gindelsky, 2017](#)). In the context of Spanish America, [Mahoney \(2010\)](#) notes that new areas were being populated after the 1760s, both through international and intra-national migration. Since I do not find an impact of increased trade with Europe on the slave trade, I make no distinction between different types of labor in the model. The model therefore implicitly assumes that higher real wages also increased the inflow of coerced labor.⁴² To capture these aspects of urban growth, I assume that individuals can migrate and choose cities to maximize their expected utility subject to migration costs.⁴³ The utility of an individual moving from region i to region j is given by $V_{ij} = V_j\epsilon_j / m_{ij}$ where ϵ_j is an iid draw from a Fréchet-distribution with shape parameter θ and captures individual-level heterogeneity in location preferences. Using the properties of the Fréchet-distribution, I show that this structure gives rise to a gravity equation for migration.

Scale economies. In the core areas of Spanish America, urbanization was relatively high in the 18th century, at times exceeding that of Spain ([Arroyo Abad and Zanden, 2016](#)). To capture this, the framework allows for agglomeration economies at the level of the city. A variety of factors drove agglomeration for pre-industrial cities ([Jedwab, Johnson and Koyama,](#)

⁴²The exact magnitude of migration from Europe is contested. Estimates range between 50,000 and 190,000 immigrants in the 18th century ([Mahoney, 2010](#)). [Cook \(1981\)](#) writes that migration in colonial Peru was extensive, covered large distances, and was mainly directed to large cities and mining centers. For 1613 numbers on origins of the population of Lima are provided in [Cook \(1981\)](#) and show a significant fraction born outside Lima. 271,000 victims of the transatlantic slave trade disembarked in Spanish America between 1700 and 1760 ([Eltis, 2000](#), p. 9)

⁴³Since one period corresponds to roughly a generation in the dataset (50 years), I abstract from more complex forward-looking behavior.

2020). They could reflect factors such as knowledge spillovers, input sharing, physical security, location-specific capital, or knowledge about the local environment. To allow for different sources of persistence in the model, I follow [Allen and Donaldson \(2020\)](#) and allow the scale economies to feature dynamic agglomeration economies.⁴⁴ In particular, the productivity of the city depends on the size of the city today and in the past with constant elasticities, $A_{it} = \bar{A}_i L_{it}^{\alpha_1} L_{it-1}^{\alpha_2}$. \bar{A}_i is a locational fundamental that is exogenous to the population size.

General equilibrium and steady-state. I define an equilibrium and steady-state of this economy given a geography that is made up of local fundamentals (\bar{A}_i and H_i), trade costs (τ_i), migration costs (μ_i), and past population distribution L_{i0} . Within each location all firms and individuals optimize and markets clear. In addition, an equilibrium is given by $E_t = \{L_{it}, w_{it}, V_{it}, \Pi_{it}\}_{i \in R}$ such that in each region total sales equals the total income ($w_{it}L_{it}/\mu = \sum_{j \in R} X_{ijt}$), trade is balanced ($w_{it}L_{it}/\mu = \sum_{j \in R} X_{jit}$), the total population equals the population arriving at a location ($L_{it} = \sum_{j \in R} L_{ jit}$), and the total population in the last period equals the number of people exiting a location between $t - 1$ and t ($L_{it-1} = \sum_{j \in R} L_{ijt}$). Moreover, a steady-state is an allocation such that $L_{it} = L_{it-1}$ for all cities i , hence a state in which the migration flows between cities cancel out. Intuitively, the existence of the equilibrium and steady-state depends on the strength of the agglomeration force (the local agglomeration economies) relative to the dispersion force (the availability of arable land for food production). Using results in [Allen and Donaldson \(2020\)](#) and [Allen, Arkolakis and Li \(2020\)](#), I provide conditions for the existence and uniqueness of the equilibrium and steady-state in the Appendix.

6.2 Estimation and Identification Strategy

In this section I calibrate the model to match the observed data. The model is fully parameterized by seven structural parameters and a tuple of fundamentals given by,

$$\Omega = \{\sigma, \theta, \mu, \alpha_1, \alpha_2, \bar{A}_i, H_i, \tau, m\}. \quad (9)$$

The empirical strategy to estimate Ω proceeds in four steps. First, I parameterize and match the trade and migration costs to corresponding reduced-form estimates to recover τ and m . Second, I invert the equilibrium conditions to recover $\{p_{it}^{\sigma-1}, P_{it}^{\sigma-1}, V_{it}^\theta, \Pi_{it}^\theta\}_{i \in R}$. Third, I estimate the structural version of the reduced-form equations to recover α_1 and α_2 . Then I choose σ to make the model match the reduced-form estimates of the reform. In a final step, productivities are calculated as the residuals of the estimated model. I further elaborate

⁴⁴As shown in [Allen and Donaldson \(2020\)](#), this can be micro-founded in a variety of ways including the persistence of local knowledge or durable investment in local productivity.

on the steps of this procedure as well as the underlying assumptions for identifying the parameters below.

External parameters. The first set of parameters are matched to parameters estimated without relying on the structure of the model. First, I match μ to the share of GDP derived from land for colonial Mexico and Peru ([Arroyo Abad and Zanden, 2016](#)). To the best of my knowledge, there are no estimates for how responsive migration flows are to differences in real wages across cities. I therefore use estimates for θ available for developing countries which typically range between 2 and 4 ([Morten and Oliveira, 2018; Bryan and Morten, 2019](#)). Next, I parameterize the bilateral trade and migration costs to depend on travel time. In particular, $\tau_{ijt} = T_{ijt}^\kappa$ and $m_{ij} = T_{ijt}^\lambda$ where κ and λ are the elasticities of trade and migration costs to travel time respectively. I match the shipping time elasticity in the model $(1 - \sigma)\kappa$ to the estimate in Table 4. The time elasticity for migration $-\lambda\theta$ is estimated using census data for Mexico and Argentina for the second half of the 19th century.⁴⁵ Finally, H_i is calculated as the share of arable land within 100km of the city using data from [Galor and Özak \(2015, 2016\)](#).⁴⁶

Model inversion. Given information on the city population sizes and urban nominal wages, the endogenous variables that would rationalize the observed population and wages can be recovered. Inverting the equilibrium conditions gives the following system of equations,

$$p_{it}^{\sigma-1} = \sum_{j \in R} \hat{T}_{ijt} \left(\frac{Y_{jt}}{Y_{it}} \right) P_{jt}^{\sigma-1} \quad (10)$$

$$P_{it}^{\sigma-1} = \sum_{j \in R} \hat{T}_{jit} \left(p_{jt}^{\sigma-1} \right)^{-1} \quad (11)$$

$$V_{it}^{-\theta} = \sum_{j \in R} \hat{M}_{jit} \left(\frac{L_{jt-1}}{L_{it}} \right) \Pi_j^{-\theta} = 0 \quad (12)$$

$$\Pi_i^{-\theta} = \sum_{j \in R} \hat{M}_{ijt} V_{jt}^\theta \quad (13)$$

where $\hat{T}_{ij} = T_{ij}^{\kappa(1-\sigma)}$ and $\hat{M}_{ij} = T_{ij}^{-\lambda\theta}$. It follows from [Allen and Donaldson \(2020\)](#) that given data on $\{L_{it}, L_{it-1}, w_{it}\}_{i \in R}$, the system uniquely solves for the endogenous variables $\{p_{it}^{\sigma-1}, P_{it}^{\sigma-1}, V_{it}^\theta, \Pi_i^\theta\}_{i \in R}$.

⁴⁵An alternative approach is to use data on migration during the colonial period from [Cook \(1981\)](#). These data have the advantage of overlapping with the colonial period. However, since the spatial variation is smaller (the data are only available for Peru), I chose to use the census data as the baseline approach.

⁴⁶[Hassig \(1993\)](#) operates with a hinterland spanning between 21 to 28 kilometers for a Mesoamerican city relying on tlamee transportation (human carriers). With the introduction of European modes of transportation this increased. Using the information on comparative trade costs of tlamee and mule transportation, I assume that the hinterland expanded by a factor of 4 ([Hassig \(1993\)](#), p. 216).

Table 12: Model parameters

Parameter	Value	Description
α_1	0.125***	Productivity spillover
α_2	0.028**	Historical productivity spillover
$\kappa(1 - \sigma)$	-3.13**	Elasticity of trade wrt. time
$-\lambda\theta$	-2.8*	Elasticity of migration wrt. time
σ	6.9	Elasticity of substitution
θ	3	Migration elasticity $\theta \in [2, 4]$
μ	0.45	Share of income not from agriculture

Note: The table reports the parameters baseline calibration of the model. α_1 , α_2 , and σ are estimated directly from the data of the 297 cities in the main sample. μ , and θ are taken from the literature.

Controls: Elevation, crop suitability, the location of active mines, distance to the coastline, and terrain ruggedness. **Standard errors:** Clustered at the level of the closest port. *** $p < .01$, ** $p < .05$, * $p < .1$

Estimating the scale elasticities. The historical scale elasticity can be identified using the equilibrium conditions. Combining the equilibrium conditions, taking logs and first differences to remove the influence of locational fundamentals and time-invariant factors gives,

$$\nu \Delta \ln L_{it} = -\sigma \Delta \ln \Lambda_{it} - \mu(2\sigma - 1) \Delta \ln P_{it} + \alpha_2 \mu(\sigma - 1) \Delta \ln L_{it-1}, \quad (14)$$

where $\nu = \mu + \sigma(1 - \mu) + \sigma / \theta + \alpha_1 \mu(1 - \sigma)$. An important assumption is therefore that changes in locational fundamentals are negligible throughout the reform period conditional on the controls, and can therefore be differenced out. Under this assumption, $\alpha_2 \mu(\sigma - 1) / \nu$ can be recovered from estimating the equation using ordinary least squares. To explore the validity of the underlying assumption, I consider the stability of the estimated coefficient to the inclusion of the controls used in the reduced-form analysis (which flexibly control for time-varying changes in the value of locational fundamentals). Further, I leverage the market clearing condition for the traded good to identify $(1 - \sigma)\alpha_1$. σ is identified by simulating the model and matching the impact of the reform to the coefficient in the baseline specification of the reduced-form exercise reported in Column (4) of Table 5. Finally, again using the market clearing condition for the traded commodity, \bar{A}_i is recovered as the residual.

Results. Table 12 contains the parameters in the baseline calibration of the model. The contemporaneous and lagged agglomeration spillovers, α_1 and α_2 are found to be 0.125 and 0.028 respectively and are both estimated precisely. As a result, a one percent increase in

the contemporaneous population size, increases the productivity of the location by 0.125 percent, while an increase in the historical population size increases the productivity of the location by 0.028 percent. This is in line with the agglomeration elasticities at the city level documented in the literature (Combes and Gobillon, 2015; Allen and Donaldson, 2020).⁴⁷ The travel time elasticities of trade and migration are also found to be in line with estimates in the literature and are also precisely estimated. A one percent increase in the travel time reduces the value of bilateral trade by around three percent and bilateral migration flows by around 2 percent. For the model to reproduce the impact of changes in trade costs documented in the reduced-form, the elasticity of substitution is set to 6.9 (this can be seen in Figure 14). The estimated value of σ is in line with other estimates in the literature.⁴⁸ Lastly, the determinants of \bar{A}_i can be seen in Figure 15. While the model permits path dependence, where initial conditions determine the allocation in the long run, I find that there exists a unique equilibrium and steady-state of the model under this calibration.⁴⁹ Due to the importance of land in consumption, the uniqueness is robust to plausible changes in the calibration of the model.

6.3 Long-Distance Trade and Long-Term Persistence

To study the long-run implications of the model, consider the behavior of the economy along its growth path. Using the indirect utility function, the market clearing conditions, assuming that trade costs are quasi-symmetric, and iterating backward gives the following relationship for the city size in equilibrium,

$$\begin{aligned} \ln L_{it} = \kappa'_i + \left(\frac{\alpha_2 \mu (\sigma - 1)}{\nu} \right)^T \ln L_{i0} - \frac{\sigma}{\nu} \sum_{k=0}^{T-1} \left(\frac{\alpha_2 \mu (\sigma - 1)}{\nu} \right)^k \ln \Lambda_{it-k} \\ - \frac{\mu (2\sigma - 1)}{\nu} \sum_{k=0}^{T-1} \left(\frac{\alpha_2 \mu (\sigma - 1)}{\nu} \right)^k \ln P_{it-k}. \end{aligned} \quad (15)$$

This equation gives the equilibrium population size of city i as a function of the history of the city, or the full path of endogenous and exogenous variables. Intuitively, the equilibrium size of the city is larger if it has a history of high productivity, availability of arable land (both captured by κ'_i), larger historical population size (L_{i0}), and better historical access to trading opportunities (P_{ik}). The local price index summarises the role of trade costs in city

⁴⁷The fact that α_1 is greater than 0.1 can be explained by the model not incorporating variety gains from population growth which could have been important Krugman (1991b). As a result, these gains are potentially incorporated into the α_1 parameter.

⁴⁸For example, Eaton and Kortum (2002) find values between 3 and 12.

⁴⁹As shown in the Appendix, the calibration is well within the set of parameter values that permit a unique equilibrium and steady-state.

growth and as a result, all changes in trade costs affect the urban growth through this term. Equation 15 can be interpreted as the structural version of Equation 4 and 5. The derivations are provided in the Appendix.

The model can account for the four facts documented in the reduced-form exercise. First, consider the impact of a change in historical trade costs to Europe at time k , denoted by τ_{iek} , on the population size of the city i at time t . Note, that the elasticity of city size at time t to a change in the price index at time k is given by $-(\mu(2\sigma - 1) / \nu)(\alpha_2\mu(\sigma - 1) / \nu)^k < 0$. Since the price index is increasing in the trade cost to Europe in period k , that is $\partial P_{ik} / \partial \tau_{iek} > 0$, it follows that lower historical trade costs to Europe increase the population size in period t which is consistent with Fact 2. As a result, historical trade costs matter for the location of economic activity in the long run.

What drives the persistence of historical patterns of trade? Since $(\alpha_2\mu(\sigma - 1) / \nu) < 1$, it follows that $\lim_{d \rightarrow \infty} \partial L_{it} / \partial \tau_{iek-d} = 0$. Hence, the impact of historical trading opportunities dissipates over time. The results are therefore not consistent with the persistence of historical trade costs being induced by multiple equilibria and lock-in effects. Rather, the data are more consistent with persistence being generated by a slow process of adjustment to a new equilibrium. This is ultimately a result of weak agglomeration forces relative to the importance of land in pre-industrial contexts. Furthermore, consistent with Fact 3, the impact of a change in the historical trade cost is attenuated by the internal market size. Since $\partial P_{ik} / \partial L_{ik} < 0$, it follows that, $\partial^2 \ln L_{it} / \partial \tau_{iek} \partial L_{ik} > 0$. As a result, the historical location of trading opportunities is more important for historically larger cities. In other words, the model shows that the persistence of historical trading opportunities depends on initial urbanization patterns as a location experiences changes in trade costs.

Finally, consider the variation in the persistence of historical settlement patterns documented in Fact 4. The model can be used to explore the determinants of the persistence of historical settlement patterns. Since the coefficient $\alpha_2\mu(\sigma - 1) / \nu$ is informative about whether the equilibrium spatial distribution of economic activity is uniquely pinned down by locational fundamentals (in which case shocks to L_{i0} will dissipate over time) or whether there are multiple equilibria (in which case shocks to L_{i0} can accumulate over time), the elasticity of L_{it} with respect to L_{i0} is of interest.⁵⁰ However, Equation 15 shows that to recover this parameter, the whole historical path of trade costs needs to be controlled for. Since the history of trade costs is unobserved, this can change the observed relationship between the historical and contemporary population size. Consider a change in trade costs at time $t - 1$ that induces a 10 percent reduction in the price index. This will induce a 11 percent reduction in the observed persistence of L_i between the two periods t . Furthermore, since changes in trade costs have larger effects in smaller locations, changes in trade costs attenuate the

⁵⁰From Equation 15, it is clear that this elasticity is given by $(\alpha_2\mu(\sigma - 1) / \nu)^T$.

persistence in the location of economic activity. Taken together, permanent trade cost shocks promote reversals rather than persistence in the location of economic activity by having a larger effect on economic growth in smaller locations.

7 Conclusion

Historical patterns of trade can play a key role in shaping city location and growth. Situated on an island, Mexico City's growth was greatly facilitated by lake-based canoe trade, which enabled access to a larger economic hinterland than that of other Mesoamerican cities (Hassig, 1993). Physical changes to the landscape have resulted in the disappearance of the lakes, yet the primacy of Mexico City persists. In contrast, Argentina's growth, which depended on trade with upper Peru for much of the colonial period, was reoriented toward the Atlantic starting in the second half of the 18th century (Scobie, 1971). Do historical patterns of trade dictate the location and size of cities today despite the marked change in patterns of trade?

In this paper, I seek answers to these questions by leveraging the reorganization of long-distance trade in the Spanish Empire during the second half of the 18th century. I combine a difference-in-differences design with a parsimonious dynamic spatial general equilibrium model that I calibrate to match the observed data. I find that the reform induced population growth by lowering the price of traded goods, but had a smaller effect on the cost of living in locations with a larger home market. Furthermore, changes in trade costs attenuated the persistence of the pre-reform settlement pattern by disproportionately increasing economic growth in smaller cities. Finally, I find that the persistence of the pre-reform settlement pattern is not driven by self-sustaining agglomerations arising around central pre-reform trading locations, but by a slow convergence to the new steady-state. In conclusion, the findings provide evidence that the location of economic activity can adapt to changes in the location of trading opportunities, but can persist when these changes are preceded by urban growth.

The empirical context provides a unique setting in which to study the long-term adjustment to changes in the location of trading opportunities, but it also has important limitations. First, the estimation of causal effects relies on sizeable and abrupt changes in trade costs which may have induced different adjustment processes than more gradual changes. Second, the sources of persistence are likely to be different in economies that do not devote substantial resources to agriculture. Other mechanisms and magnitudes might be important in more industrialized contexts with stronger agglomeration economies. These issues are potentially interesting avenues for future research.

8 Tables

Table 1: Summary statistics of the city-panel

Statistic	N	Mean	St. Dev.	Min	Median	Max
Population	1,566	6,502.42	14,204.01	400.00	2,000.00	200,000.00
Shipping time 1760 (days)	1,782	58.62	17.90	34.86	54.08	145.27
Shipping time 1810 (days)	1,782	53.80	17.32	26.02	51.93	143.18
Δ Shipping time (days)	1,782	4.82	6.61	0.00	1.91	27.32
Elevation	1,782	0.24	0.43	0	0	1
Terrain ruggedness	1,782	263.33	221.74	2.04	215.08	1,033.84
Average crop suitability	1,782	0.00	1.00	-1.52	-0.11	2.76
Mining center	1,782	0.07	0.26	0	0	1
Average temperature (celsius)	1,782	20.98	4.90	4.52	21.92	28.49
Precipitation (mm.)	1,782	1,408.01	1,223.49	3.06	1,088.19	7,292.16
Coffee	1,782	6.75	1.22	3	6.8	8
Tobacco	1,782	6.31	1.16	2.69	6.26	8.08
Cotton	1,782	6.36	1.32	1	6.3	8
Wheat	1,782	6.84	1.49	2.51	7.67	8.18
Maize	1,782	5.74	1.34	2	5.9	8
Sugar cane	1,782	6.64	1.30	3	6.8	8
Distance to coast (km)	1,782	175.68	190.04	2.02	100.89	988.70
Distance to river (km)	1,782	458.61	340.09	1.19	381.30	1,303.24
Distance to port in 1750 (km)	1,782	304.28	370.87	5.45	192.80	2,516.95
Decade	1,782	1,725.00	85.42	1,600	1,725	1,850

Note: The table reports summary statistics of the key variables used in the analysis. The unit of analysis is the city. The dataset is a panel at a 50-year frequency for the period 1600-1850 for 297 cities. *Elevation* is an indicator variable equal one if the elevation is above 1500m. *Crop suitability* is the average suitability for tobacco, cotton, sugar cane, cacao, and coffee (standardized).

Table 2: Summary statistics of the grid-cell dataset

Statistic	N	Mean	St. Dev.	Min	Median	Max
#Settlements	55,154	0.21	0.84	0	0	25
Population 1760	55,154	2,098.00	5,707.89	0.00	165.76	118,175.10
Population 1810	55,154	2,469.52	6,824.08	0.00	234.46	142,383.30
Shipping time 1760 (days)	55,154	83.08	25.19	35.49	82.19	158.67

Maize	55,154	6.16	1.66	1.00	6.13	8.75
Sugar cane	55,154	6.76	1.44	1	7.8	9
Distance to coast (km)	55,154	412.17	317.95	0.19	336.61	1,471.73
Distance to river (km)	55,154	387.57	436.48	0.02	226.78	2,481.35
Distance to port in 1750 (km)	55,154	812.69	673.36	3.76	621.79	3,157.83
Decade	55,154	1,760.00	31.62	1,710	1,760	1,810

Note: The table reports the main variables used in the analysis. The unit of analysis is at the grid-cell level. The dataset is a balanced panel at a 10 year frequency for the period 1710-1810 for 5,014 grid cells ($5,014 \times 11 = 55,154$). *Elevation* is an indicator variable equal one if the elevation is above 1500m. *Crop suitability* is the average suitability for tobacco, cotton, sugar cane, cacao, and coffee (standardized).

Table 3: Ports 1700 - 1810

Port	Country	Direct trade (decade)	Longitude	Latitude
Cadiz	Spain	<1700	-6.28	36.53
Acapulco	Mexico	<1700	-99.91	16.85
Portobelo	Panama	<1700	-79.65	9.55
Panama	Panama	<1700	-79.53	8.95
El Callao	Peru	<1700	-77.15	-12.06
Cartagena de Indias	Colombia	<1700	-75.55	10.42
Veracruz	Mexico	<1700	-96.14	19.19

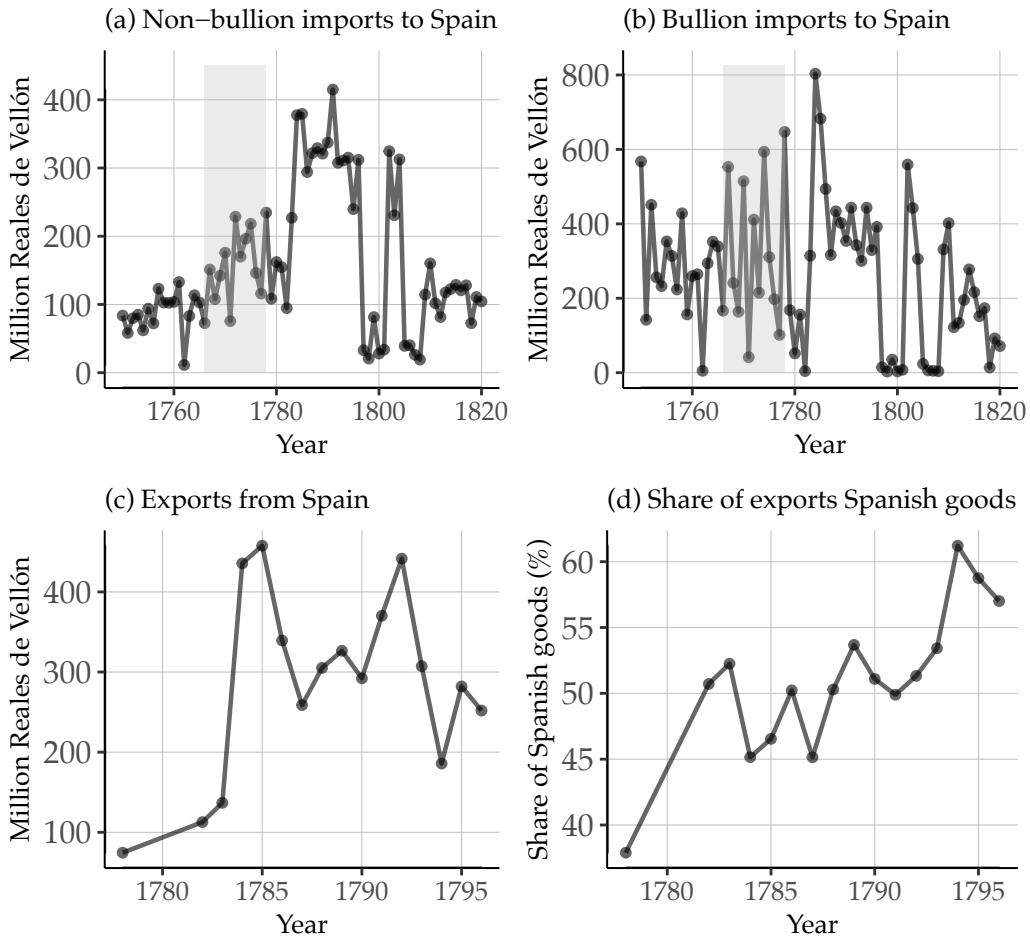

Figure 2: Panel (a) displays the value of private non-bullion imports to Spain (in million reales de vellón) from American ports between 1750 and 1820 at constant prices. Panel (b) displays private bullion imports to Spain between 1750 and 1820 at constant prices. The shaded area denotes the main reform period. The large drop in 1797 is due to the British blockade of Cadiz as part of the Anglo-Spanish War 1796-1808. The lower level after 1807 was due to the Peninsular War as well as the Spanish-American wars of independence. Data for 1780 is missing in the original data source (imputed with average). Panel (c) displays exports from Spain for the years 1782 to 1796. Panel (d) displays the share of Spanish exports originating in Spain for the years 1782 to 1796. Source: [Cuenca-Esteban \(2008\)](#) and [Fisher \(1985\)](#).

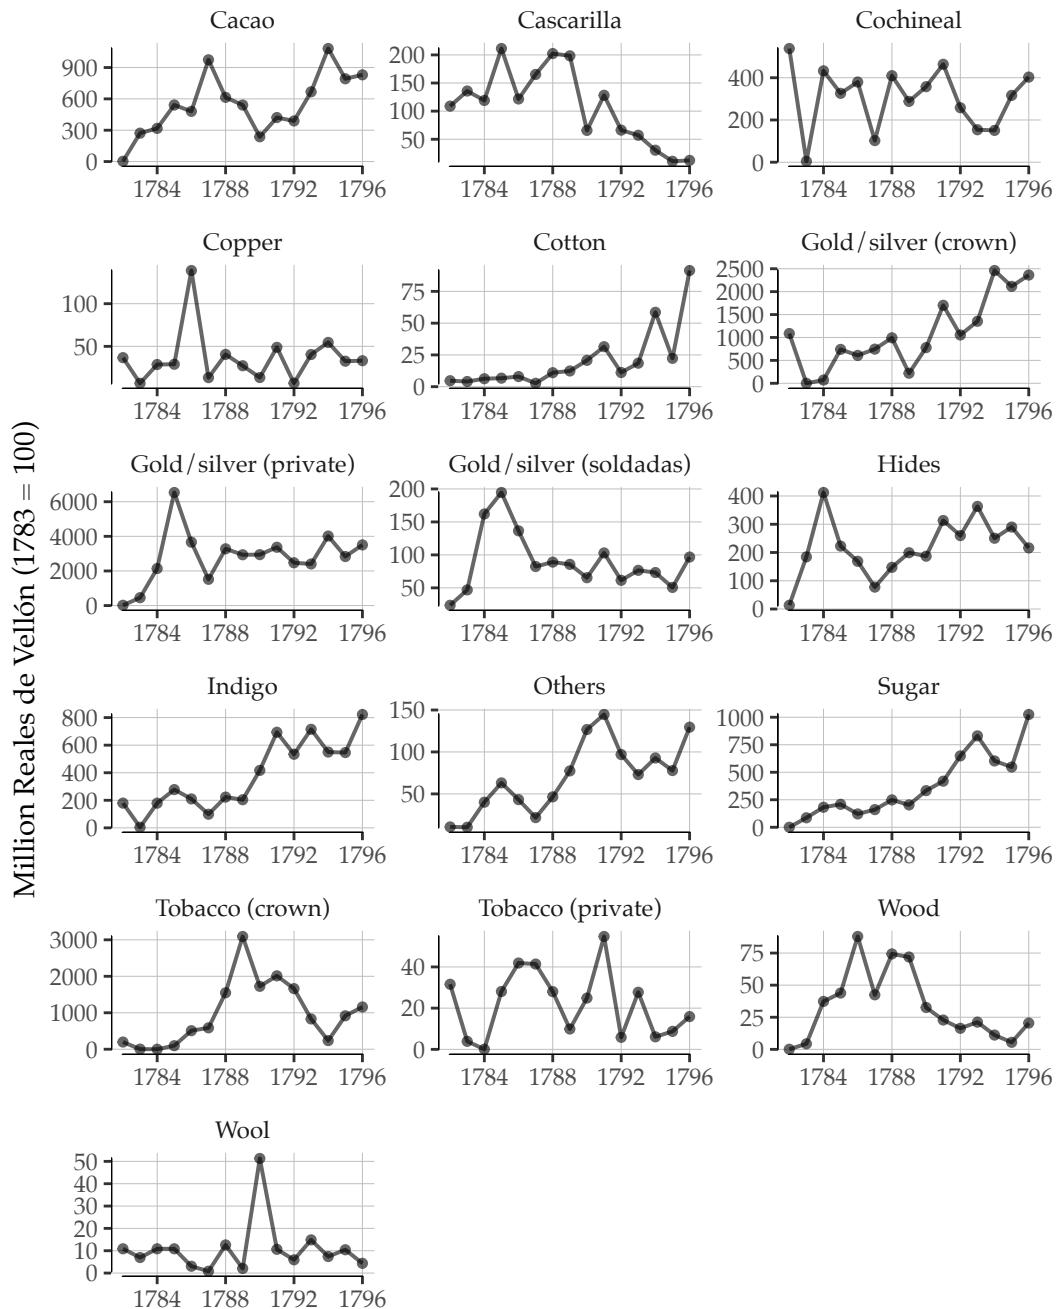

Figure 3: The figure depicts the imports to Cadiz of various commodities (in million reales de vellón) for the years 1782 to 1796. Source: Fisher (1985).

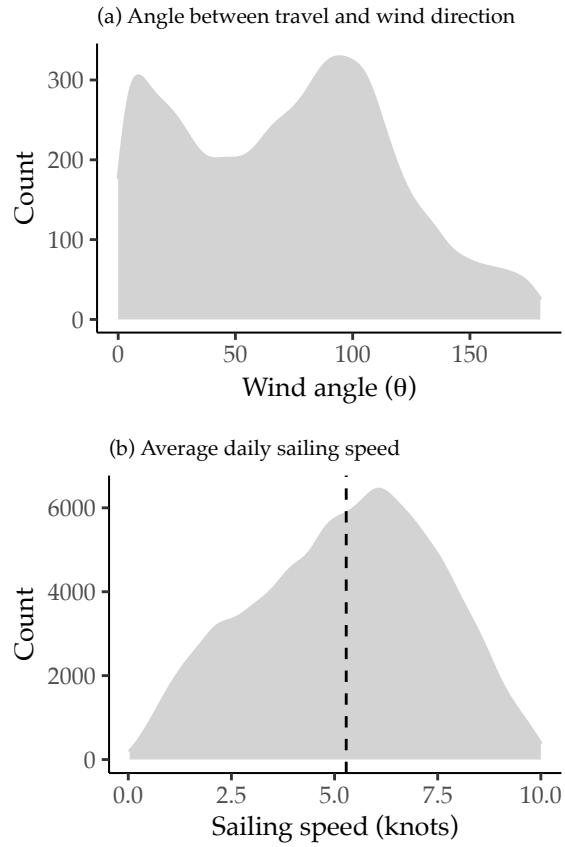

Figure 4: Panel (a) depicts the deviation of the sailing direction and wind direction for the logbook entries. Panel (b) depicts the average daily speed imputed from the logbook entries. The vertical line denotes the average sailing speed in the sample.

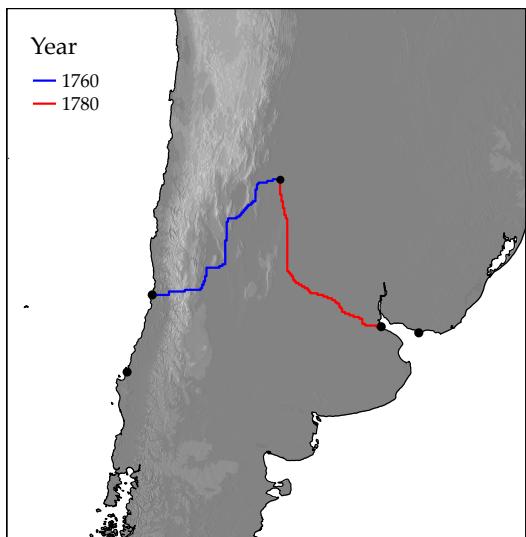

Figure 5: The figure depicts the time minimizing route from a location in current day Argentina to Europe in 1760 (blue) and 1810 (red).

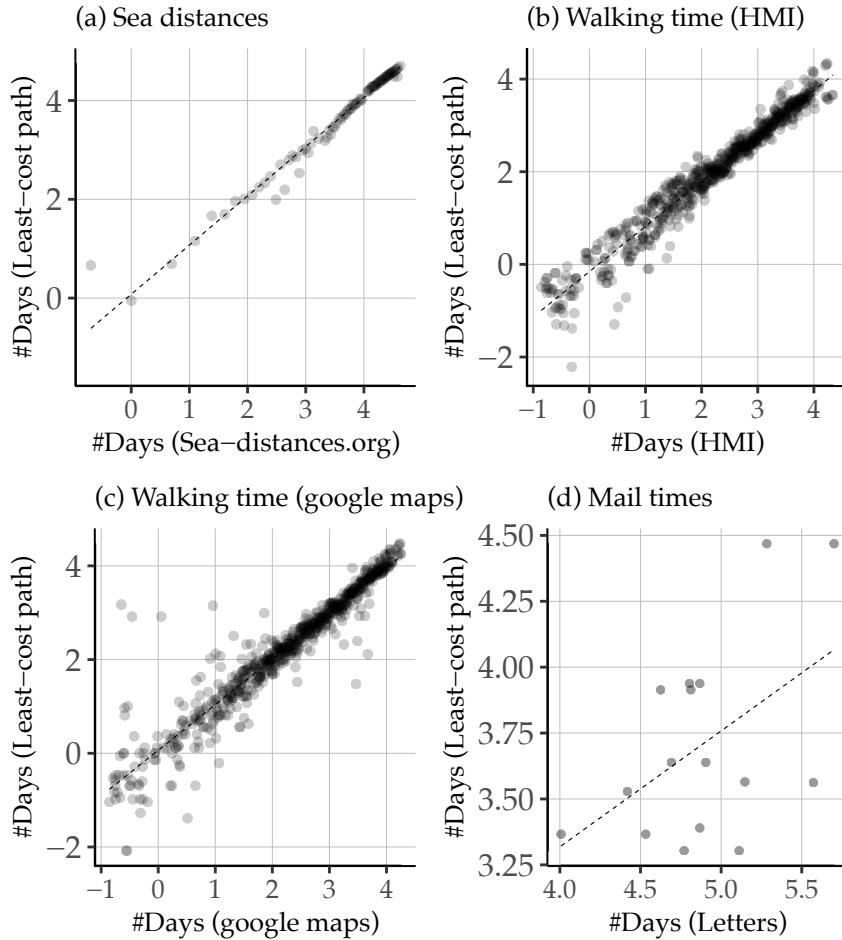

Figure 7: The figures depict the results from the main validation exercises. Panel (a) depicts the relationship between sailing times produced by the least-cost path on the constructed cost-surface and sailing times from sea-distances.org for voyages between Cadiz and 21 ports in Spanish America. The travel times are set to 4 knots which is the average speed attained over the cost-surface. Panel (b) depicts the relationship between bilateral shipping times between large cities generated by the least-cost path on the constructed cost-surface and the Human Mobility Index developed in Özak (2010, 2018). Panel (c) depicts the relationship between bilateral shipping times between major cities generated by the least-cost path on the constructed cost-surface and google maps. Panel (d) shows the relation between the shipping and the time for letters to arrive from various ports.

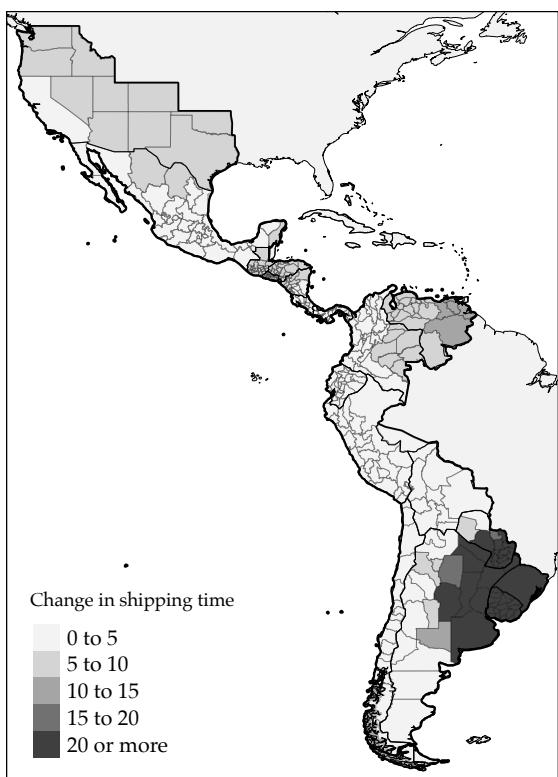

Figure 8: The figure depicts the difference between shipping times in 1760 and 1810 aggregated to the province-level. Darker colors indicate larger reductions in shipping times. Lines denote country and province borders.

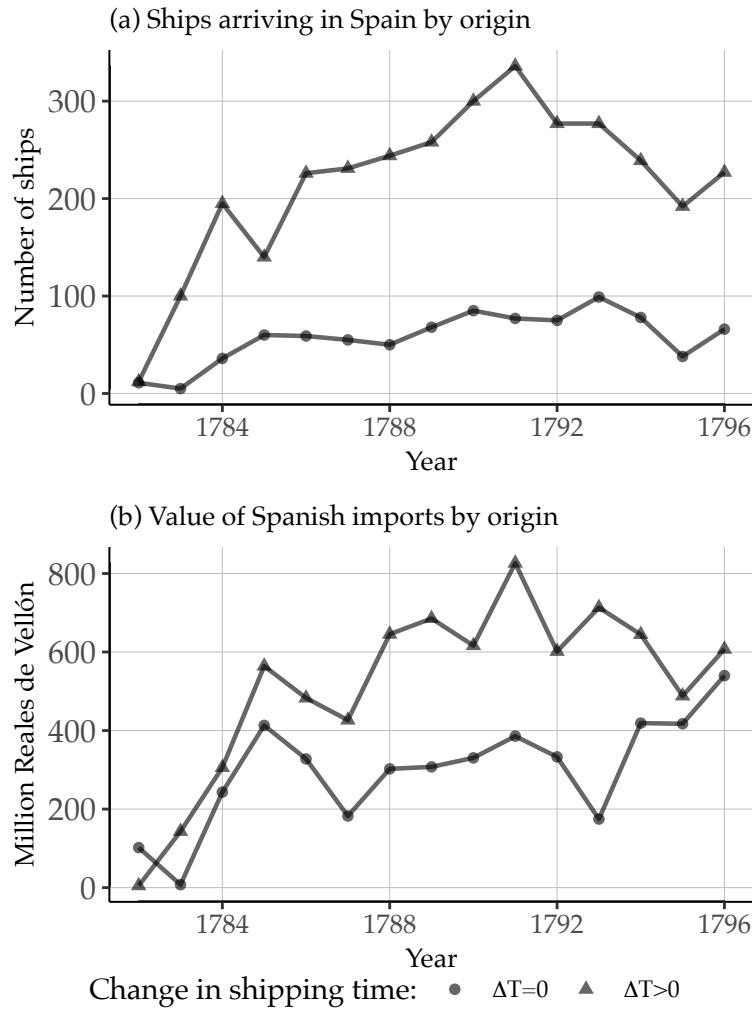

Figure 9: Panel (a) displays the number of ships arriving in Cadiz from ports experiencing changes in shipping time as a result of the reform ($\Delta T > 0$) and ports without changes in the shipping time ($\Delta T = 0$) for the years 1782 to 1796. Panel (b) displays the value of imports arriving in Cadiz (in million reales de vellón) from ports experiencing changes in shipping time as a result of the reform ($\Delta T > 0$) and ports without changes in the shipping time ($\Delta T = 0$) for the years 1782 to 1796. Source: Fisher (1985).

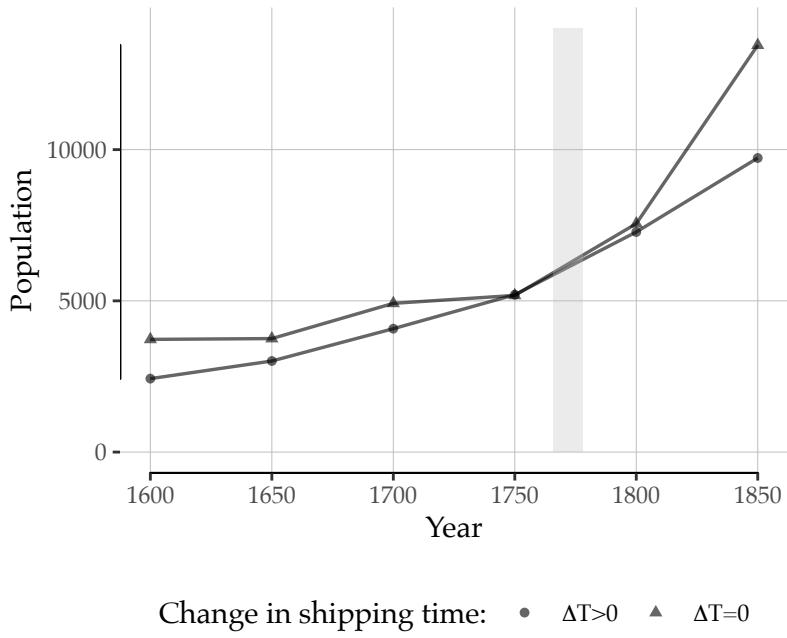

Figure 10: The figure depicts the average population size for cities with changes in the shipping time to Europe and cities without changes in the shipping time to Europe. The shaded area shows the main period of the reform.

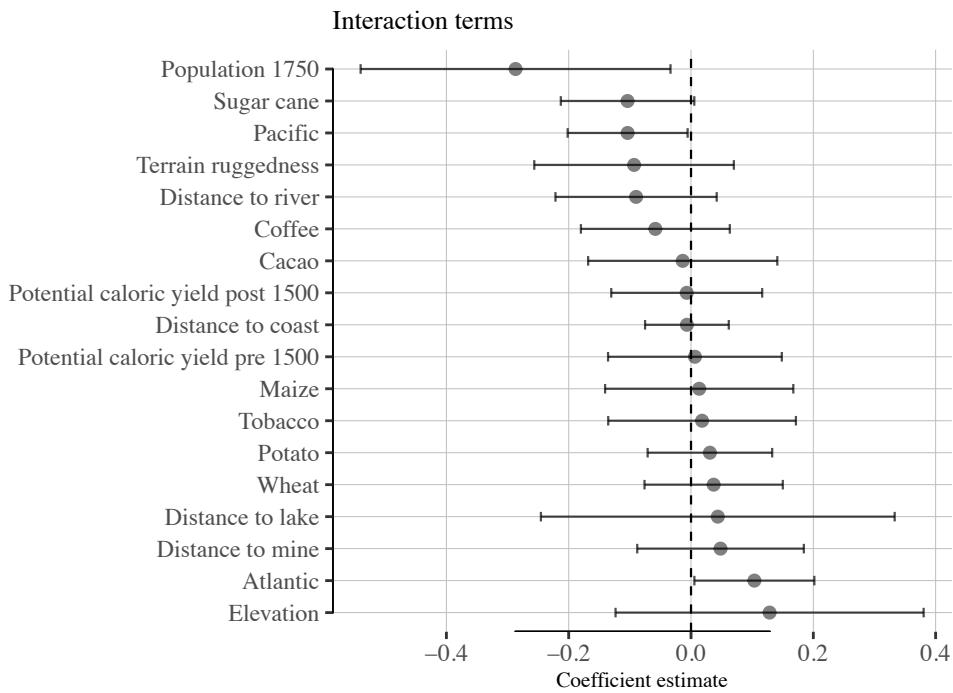

Figure 11: The figure depicts the interaction between the decline in shipping time and a range of variables as well as their 95 percent confidence intervals. Each point is the coefficient from a regression where population growth between 1750 and 1850 is regressed on each variable interacted with the decline in shipping time (ΔT) using the baseline specification. All variables are standardized to facilitate comparison.

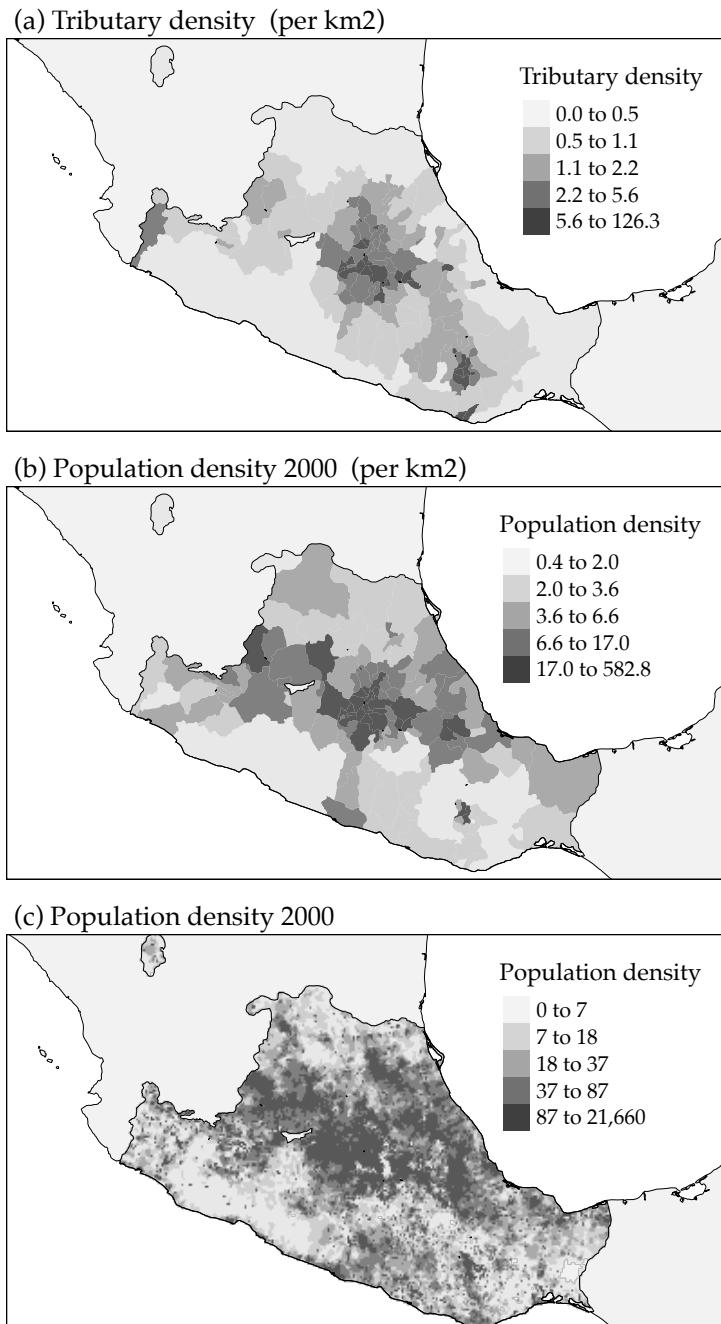

Figure 12: The figure depicts the population density and tributary density for central Mexico. Panel (a) depicts the tributary density by political division for the colonial era. Data are from [Gerhard \(1993a\)](#). Panel (b) depicts the population density aggregated to the same political boundaries in 2000. Panel (c) shows the underlying raster containing population density for 2000.

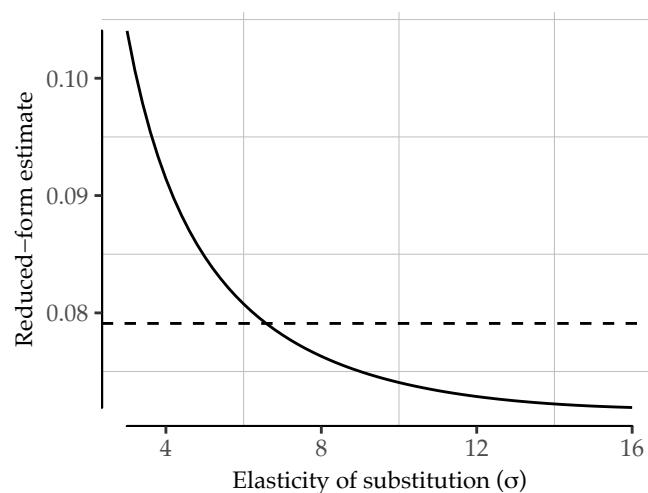

Figure 14: The figure depicts the model-implied impact of the reform for different values of σ . The magnitude of the reduced-form estimate in the baseline specification reported in Column (4) of Table 5 is denoted by the horizontal line.

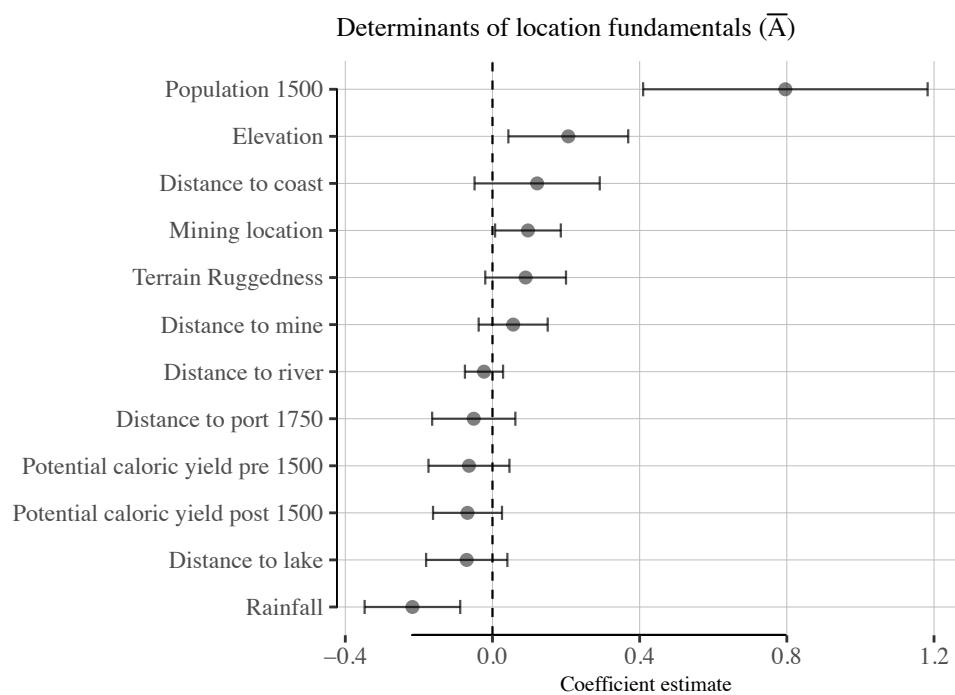

Figure 15: The figure depicts the correlates of the locational fundamentals implied by the model (\bar{A}) and 95 percent confidence intervals. Each point is the coefficient of the locational fundamental regressed on each variable. The variables are standardized.

A Model Derivation

This section shows the main steps of the derivation of the model, the equilibrium conditions, and the estimation of the parameters.

Preferences. The consumers' problem is standard and I outline the main steps in this section. The utility function is defined over a composite of traded goods that are specific to each location (the Armington assumption) and food that is sourced from the immediate hinterland and is therefore non-traded. These preferences take the Cobb-Douglas form and are defined as follows,

$$U_i = \frac{C_i^\mu F_i^{1-\mu}}{\mu^\mu (1-\mu)^{1-\mu}}, \quad (\text{A.1})$$

where $C_i = \left(\sum_{j \in N} c_{ji}^{\frac{\sigma-1}{\sigma}} \right)^{\frac{\sigma}{\sigma-1}}$ and c_{ji} is the amount of the location j specific good consumed in location i . Since Y_i is the total income in region i , p_{ji} is the price of the j -good in location i , and r_i is the price of land, the demand for food is given by $F_i = (1-\mu)Y_i / r_i$ and the demand for the traded composite good is given by $C_i = \mu Y_i / P_i$. To find the demand function for each location-specific good I solve the following problem (where time subscripts are suppressed for legibility),

$$\max_{\{c_{ji}\}_{j=1}^R} \left(\sum_{j \in R} c_{ji}^{\frac{\sigma-1}{\sigma}} \right)^{\frac{\sigma}{\sigma-1}} \text{ s.t. } \sum_{j \in R} c_{ji} p_{ji} \leq E_i, \quad (\text{A.2})$$

where E_i is the aggregate expenditure on the traded good in region i . As a result, $c_{ji} = p_{ji} Y_i P_i^{\sigma-1}$ where $P_i = \left(\sum_{j \in N} p_{ji}^{1-\sigma} \right)^{\frac{1}{1-\sigma}}$ and denotes the price index for the traded good. Inserting the demand functions into the utility function gives the indirect utility function for an individual in location i that is provided in the paper,

$$V_i = \frac{w_i}{P_i^\mu r_i^{1-\mu}}. \quad (\text{A.3})$$

Production. Production takes place under perfect competition and as a result the price for traded and non-traded goods is equal to its marginal cost. Since a worker in location i can produce A_i units of a good and the wage is w_i , the price of the good in location i is given by $p_i = w_i / A_i$. Since there are iceberg transportation costs, the price faced by an individual in location i is given by $p_{ji} = \tau_{ji} w_j / A_j$. A_i consists of both an exogenous location specific component (\bar{A}_i) and an endogenous component of non-pecuniary externalities not internalized by the production entity which depends on the size of the city i . The productivity of location i at time t is therefore given by $A_{it} = \bar{A}_i L_{it}^{\alpha_1} L_{it-1}^{\alpha_2}$. Finally, the use of land in the production of food features constant returns to scale and is a function of the availability of arable land H_i which is exogenous in each location. As a result, $F_i = H_i$. The land market is perfectly competitive. Since the market for land is competitive and supply exogenous, the price for land is pinned down by the demand function for F_i is given by $r_i = (1-\mu)Y_i / H_i$.

Trade. Assuming market clearing such that $c_{ji} = q_{ji}$, the value of trade from location j to location i is given by $X_{ji} = q_{ji} p_{ji} = p_{ji}^{1-\sigma} \mu Y_i P_i^{\sigma-1} = \left(\tau_{ji} \frac{w_j}{A_j} \right)^{1-\sigma} \mu Y_i P_i^{\sigma-1}$ where q_{ji} denotes the number of units of the location j goods that arrive in location i . Using the expression for the local productivity A_i and that $\mu Y_i = w_i L_i$ in equilibrium gives the expression in the derivations that follow.

Labor mobility. The utility of an individual moving from region i to region j is given by $V_{ij} = \frac{V_i}{m_{ij}} \epsilon_j$ where ϵ_j is an

idiosyncratic taste shifter, assumed to be an iid draw from a Fréchet-distribution with shape parameter θ capturing individual level heterogeneity in location preferences. An individual chooses to move from i to j if the realized utility of that location is higher, which happens with probability $Pr(V_{ij}\epsilon_j \geq V_{ik}\epsilon_k \forall k \neq j \in R)$. Since the idiosyncratic location preferences are iid and there is a continuum of agents in each location this probability corresponds to the share of agents in city i moving to j , denoted π_{ij} . It follows that the conditional probability of moving is,

$$\pi_{ij}|\epsilon_j = Pr\left(\epsilon_k \leq \frac{V_{ij}\epsilon_j}{V_{ik}} \epsilon_k \forall k \neq j \in R\right) = \prod_{k \neq j} Pr\left(\epsilon_k \leq \frac{V_{ij}\epsilon_j}{V_{ik}}\right). \quad (\text{A.4})$$

As a result, the unconditional distribution is given by,

$$\pi_{ij} = \int_0^\infty f(\epsilon_j) \prod_{k \neq j} Pr\left(\epsilon_k \leq \frac{V_{ij}\epsilon_j}{V_{ik}}\right) d\epsilon_j = \int_0^\infty \theta \epsilon_j^{-1-\theta} \exp\{-\epsilon_j^{-\theta}\} \exp\{-V_{ij}^{-\theta} \epsilon_j^{-\theta} \sum_{k \neq j} V_{ik}^\theta\} d\epsilon_j \quad (\text{A.5})$$

$$= \int_0^\infty \theta \epsilon_j^{-1-\theta} \exp\{-\epsilon_j^{-\theta} \Phi_j\} d\epsilon_j = \Phi_j^{-1} = \frac{V_{ij}^\theta}{\sum_{k \in R} V_{ik}^\theta} = \frac{(V_j / m_{ij})^\theta}{\sum_{k \in R} (V_k / m_{ik})^\theta}, \quad (\text{A.6})$$

which follows after making the substitution defining $x = \epsilon_j^{-\theta} \Phi_j$. The expected utility (prior to the realization of shocks) for an agent living in location i is given by $E[\max_{j \in R} V_{ij}]$. To derive the expression define ψ_{ij} which gives the utility expected to be derived from location j . It follows that $\psi_{ij}|\epsilon_j = V_{ij}\epsilon_j Pr\left(\epsilon_k \leq \frac{V_{ij}\epsilon_j}{V_{ik}} \epsilon_k \forall k \neq j \in R\right) = V_{ij}\epsilon_j \prod_{k \neq j} Pr\left(\epsilon_k \leq \frac{V_{ij}\epsilon_j}{V_{ik}} \epsilon_k\right)$. As a result, the unconditional expectation is given by,

$$\psi_{ij} = \int_0^\infty f(\epsilon_j) V_{ij}\epsilon_j \prod_{k \neq j} Pr\left(\epsilon_k \leq \frac{V_{ij}\epsilon_j}{V_{ik}}\right) d\epsilon_j. \quad (\text{A.7})$$

Again using the distributional assumptions and rearranging gives

$$\psi_{ij} = \theta V_{ij} \int_0^\infty \epsilon_j^{-\theta} \exp\{-\epsilon_j^{-\theta} \Phi_j\} \epsilon_j. \quad (\text{A.8})$$

Substituting with $x = \epsilon_j^{-\theta} \Phi_j$, it follows that $\psi_{ij} = CV_{ij}\Phi_j^{\frac{1-\theta}{\theta}}$. Then summing over ψ_{ij} gives $\Pi_i = \sum_{k \in R} \psi_{ik} = \left(\sum_{k \in R} V_{ik}^\theta\right)^{\frac{1}{\theta}}$. The number of people moving from i to j is the $L_{ijt} = \pi_{ij}L_{it-1} = L_{it-1}V_j^\theta \Pi_i^{-\theta} m_{ij}^{-\theta}$ which is the gravity equation for migration in the model.

Equilibrium. The equilibrium of the model is characterized by the following six equations.

1. $w_i L_i = \sum_{k \in N} X_{ik}$. The expenditure total on goods produced in i equals the revenue in each location, which in turn equals the cost of labor when there are zero profits (goods market clearing).
2. $w_i L_i = \sum_{k \in N} X_{ki}$. Revenue from trade equals total expenditure on goods (balanced trade in each location).
3. $Y_i = \frac{w_i L_i}{\mu}$. Total income in each location equals income derived from land and labor (labor and land market clearing condition).
4. $\sum_{k \in N} L_i = \bar{L}$. The total population size of the economy is fixed.
5. $L_i = \sum_{k \in N} L_{ji}$. The total population equals the number arriving at the location.
6. $L_{it-1} = \sum_{k \in N} L_{ijt}$. The total population equals the number exiting that location.

Since trade is balanced and trade costs are quasi-symmetric, it follows that the origin and destination terms in the gravity equation are proportional (Allen and Arkolakis, 2014). Therefore $w_i^{1-\sigma} A_i^{\sigma-1} \propto w_i L_i P_i^{\sigma-1}$. Using the indirect

utility, it follows that $P_i^{\sigma-1} = w_i^{\sigma-1} V_i^{\frac{1-\sigma}{\mu}} H_i^{\frac{(1-\mu)(\sigma-1)}{\mu}} L_i^{\frac{(\mu-1)(\sigma-1)}{\mu}}$. Inserting this gives the following expression for the nominal wage,

$$w_i = A_i^{\tilde{\sigma}} L_i^{\tilde{\sigma}(\frac{1}{1-\sigma} + \frac{1-\mu}{\mu})} V_i^{\frac{\tilde{\sigma}}{\mu}} H_i^{\frac{(\mu-1)\tilde{\sigma}}{\mu}}. \quad (\text{A.9})$$

Using the goods market clearing condition, it follows that

$$w_i L_i = \sum_{j \in R} \tau_{ij}^{1-\sigma} w_i^{1-\sigma} A_i^{\sigma-1} L_j w_j P_j^{\sigma-1} \quad (\text{A.10})$$

$$A_i^{\tilde{\sigma}\sigma+1-\sigma} L_i^{1+\tilde{\sigma}\sigma(\frac{1}{1-\sigma} + \frac{1-\mu}{\mu})} V_i^{\frac{\tilde{\sigma}\sigma}{\mu}} H_i^{\frac{(\mu-1)\tilde{\sigma}\sigma}{\mu}} = \sum_{j \in R} \tau_{ij}^{1-\sigma} A_j^{\tilde{\sigma}\sigma} L_j^{1+\tilde{\sigma}\sigma(\frac{1}{1-\sigma} + \frac{1-\mu}{\mu})} V_j^{\frac{\tilde{\sigma}\sigma}{\mu}} H_j^{\frac{\mu-1}{\mu}} (\tilde{\sigma}\sigma - \sigma + 1) \quad (\text{A.11})$$

Using the functional form of the agglomeration spillovers then results in the following equations for the equilibrium of the model,

$$L_i^{\tilde{\sigma}(1-\sigma\frac{\mu-1}{\mu} - \alpha_1(\sigma-1))} V_i^{\frac{\tilde{\sigma}\sigma}{\mu}} = A_i^{\tilde{\sigma}(\sigma-1)} H_i^{\frac{(1-\mu)\tilde{\sigma}\sigma}{\mu}} L_{it-1}^{\alpha_2\tilde{\sigma}(\sigma-1)} \sum_{j \in R} \tau_{ij}^{1-\sigma} \bar{A}_j^{\tilde{\sigma}\sigma} L_j^{\tilde{\sigma}(1+\alpha_1\sigma + \frac{(\sigma-1)(1-\mu)}{\mu})} V_j^{\frac{\tilde{\sigma}(1-\sigma)}{\mu}} H_j^{\frac{\tilde{\sigma}(\mu-1)(1-\sigma)}{\mu}} L_{jt-1}^{\sigma\tilde{\sigma}\alpha_2} \quad (\text{A.12})$$

$$\Pi_i^\theta = \sum_{j \in R} m_{ij}^{-\theta} V_j^\theta \quad (\text{A.13})$$

$$L_i V_i^{-\theta} = \sum_{j \in R} m_{ij}^{-\theta} \Pi_j^{-\theta} L_{jt-1} \quad (\text{A.14})$$

Existence and uniqueness. The set of model parameters that guarantee uniqueness and existence of the equilibrium can be derived using the results in [Allen and Donaldson \(2020\)](#) and [Allen, Arkolakis and Li \(2020\)](#). There are $3 \times R$ endogenous variables that need to be solved for. Ordering the endogenous variables as L , V , and Π gives the following matrices of coefficients,

$$\mathbf{B} = \begin{bmatrix} \tilde{\sigma}(1 - \sigma \frac{\mu-1}{\mu} - \alpha_1(\sigma-1)) & \frac{\tilde{\sigma}\sigma}{\mu} & 0 \\ 0 & 0 & \theta \\ 1 & -\theta & 0 \end{bmatrix}, \quad (\text{A.15})$$

$$\boldsymbol{\Gamma} = \begin{bmatrix} \tilde{\sigma}(1 + \alpha_1\sigma + \frac{(\sigma-1)(1-\mu)}{\mu}) & \frac{\tilde{\sigma}(1-\sigma)}{\mu} & 0 \\ 0 & \theta & 0 \\ 0 & 0 & -\theta \end{bmatrix}, \quad (\text{A.16})$$

It follows that the inverse of \mathbf{B} is given by,

$$\mathbf{B}^{-1} = \frac{1}{\theta^2 b_{11} + \frac{\tilde{\sigma}\sigma\theta}{\mu}} \begin{bmatrix} \theta^2 & 0 & \frac{\tilde{\sigma}\sigma\theta}{\mu} \\ \theta & 0 & -\theta b_{11} \\ 0 & \theta b_{11} + \frac{\tilde{\sigma}\sigma}{\mu} & 0 \end{bmatrix}, \quad (\text{A.17})$$

where $b_{11} = \tilde{\sigma}(1 - \sigma \frac{\mu-1}{\mu} - \alpha_1(\sigma-1))$. As a result,

$$\boldsymbol{\Gamma} \mathbf{B}^{-1} = \frac{1}{b_{11}\theta^2 + \frac{\tilde{\sigma}\sigma\theta}{\mu}} \begin{bmatrix} \theta^2 \Gamma_{11} + \frac{\theta\tilde{\sigma}(1-\sigma)}{\mu} & 0 & \frac{\Gamma_{11}\tilde{\sigma}\sigma\theta}{\mu} - \frac{\theta b_{11}\tilde{\sigma}(1-\sigma)}{\mu} \\ \theta^2 & 0 & -\theta^2 b_{11} \\ 0 & -\theta^2 b_{11} - \frac{\tilde{\sigma}\sigma\theta}{\mu} & 0 \end{bmatrix}. \quad (\text{A.18})$$

As noted in [Allen and Donaldson \(2020\)](#), the spectral norm of the absolute value of the above matrix is equivalent to

the spectral norm of the smaller matrix,

$$\mathbf{A}^p = \left| \frac{1}{\theta^2 b_{11} + \frac{\tilde{\sigma}\sigma\theta}{\mu}} \right| \begin{bmatrix} \left| \theta^2 \Gamma_{11} + \frac{\theta\tilde{\sigma}(1-\sigma)}{\mu} \right| & \left| \Gamma_{11} - \frac{\theta b_{11}(1-\sigma)}{1-\mu} \right| \\ \left| \theta^2 \right| & \left| -\theta^2 b_{11} \right| \end{bmatrix}. \quad (\text{A.19})$$

Next, consider the long-run steady state of the model. There will still be migration in the model in the steady-state, but bilateral flows will cancel out leaving the relative size of all locations fixed. The long-run steady state is characterized by $L_{it} = L_{it-1}$ for all i . Using this condition gives the following system of equations for the steady-state of the model.

$$L_i^{\tilde{\sigma}(1-\sigma)\frac{\mu-1}{\mu} - (\alpha_1 + \alpha_2)(\sigma-1)} V_i^{\frac{\tilde{\sigma}\sigma}{\mu}} = \bar{A}_i^{\tilde{\sigma}(\sigma-1)} H_i^{\frac{(1-\mu)\tilde{\sigma}\sigma}{\mu}} \sum_{j \in R} \tau_{ij}^{1-\sigma} \bar{A}_j^{\tilde{\sigma}\sigma} L_j^{\tilde{\sigma}(1+(\alpha_1+\alpha_2)\sigma + \frac{(1-\sigma)(1-\mu)}{\mu})} V_j^{\frac{\tilde{\sigma}(1-\sigma)}{\mu}} H_j^{\frac{\tilde{\sigma}(\mu-1)(1-\sigma)}{\mu}} \quad (\text{A.20})$$

$$\Pi_i^\theta = \sum_{j \in R} m_{ij}^{-\theta} V_j^\theta \quad (\text{A.21})$$

$$L_i V_i^{-\theta} = \sum_{j \in R} m_{ij}^{-\theta} \Pi_j^{-\theta} L_{jt} \quad (\text{A.22})$$

As the equations pinning down the steady-state are the same as for the equilibrium except for the parameters, the existence and uniqueness follow directly from the above condition where α_1 is replaced by $\alpha_1 + \alpha_2$. For the baseline calibration of the model, the spectral norm is given approximately 0.9 in both cases. As a result, the equilibrium and steady-state are both unique.

Reduced form relationships. The deterministic component of indirect utility is given by $V_i = w_i P_i^{-\mu} r_i^{\mu-1}$ where again $r_i = (1-\mu)w_i L_i / H_i$ and assuming quasi-symmetric trade costs $w_i^{1-\sigma} A_i^{\sigma-1} \propto w_i L_i P_i^{\sigma-1}$. As a result, $V_i^{-\sigma} = w_i^{-\mu\sigma} P_i^{\mu\sigma} L_i^{\sigma(1-\mu)} H_i^{\sigma(1-\mu)}$ and $w_i^{-\sigma\mu} \propto A_i^{\mu(1-\sigma)} L_i^\mu P_i^{\mu(\sigma-1)}$. Inserting the latter expression into the former gives and using the specification for the agglomeration economies gives,

$$L_i^{\mu+\sigma(1-\mu)+\frac{\sigma}{\theta}+\alpha_1\mu(1-\sigma)} = \kappa \Lambda_{it}^{-\sigma} \bar{A}_i^{\mu(\sigma-1)} L_{it-1}^{\alpha_2\mu(\sigma-1)} P_{it}^{\mu(1-2\sigma)} H_i^{\sigma(1-\mu)}, \quad (\text{A.23})$$

where $\Lambda_{it} = V_{it} (L_{it} / \bar{L})^{-\frac{1}{\theta}}$. Taking the natural logarithm of this expression gives

$$\nu \ln L_i = \kappa' - \sigma \ln \Lambda_{it} + \mu(\sigma-1) \ln \bar{A}_i + \alpha_2 \mu(\sigma-1) \ln L_{it-1} - \mu(2\sigma-1) \ln P_{it}, \quad (\text{A.24})$$

where $\nu = \mu + \sigma(1-\mu) + \frac{\sigma}{\theta} + \alpha_1\mu(1-\sigma)$ and κ' is a location-specific constant. Taking first differences gives the expression in the text. Next, the expression can be used recursively to solve for the current population as a function of the full path of endogenous and exogenous variables,

$$\begin{aligned} \ln L_{it} = \kappa'_i + \left(\frac{\alpha_2 \mu(\sigma-1)}{\nu} \right)^T \ln L_{i0} - \frac{\sigma}{\nu} \sum_{k=0}^{T-1} \left(\frac{\alpha_2 \mu(\sigma-1)}{\nu} \right)^k \ln \Lambda_{it-k} \\ - \frac{\mu(2\sigma-1)}{\nu} \sum_{k=0}^{T-1} \left(\frac{\alpha_2 \mu(\sigma-1)}{\nu} \right)^k \ln P_{it-k}. \end{aligned} \quad (\text{A.25})$$

To analyze the comparative statics underlying the reduced form exercise consider the above equation I consider a reduction in the trade cost to Europe in period k for city i (τ_{iek}). It follows that,

$$\frac{\partial \ln L_{it}}{\partial \tau_{iek}} = - \frac{\mu(2\sigma-1)}{\nu} \left(\frac{\alpha_2 \mu(\sigma-1)}{\nu} \right)^{t-k} P_{ik}^{\frac{2\sigma-1}{1-\sigma}} \tau_{iek}^{-\sigma} w_{ek}^{1-\sigma} A_e^{\sigma-1} < 0, \quad (\text{A.26})$$

which shows that a lower trade cost to Europe has a persistent and positive effect on the population size in location i .

Moreover, since $\alpha_2\mu(\sigma - 1) / \nu < 1$, it follows that $\lim_{t \rightarrow \infty} \partial L_{it} / \partial \tau_{iet} = 0$. Finally, I consider the effect of changes in trade for cities differing in initial market size (L_{ik}). Since $\partial P_{ik} / \partial L_{ik} < 0$, it follows that, $\partial^2 \ln L_{it} / \partial \tau_{iek} \partial L_{ik} > 0$.

B Data Sources

Urban population. This dataset on urban population sizes combines a variety of sources. Importantly for this study, the data quality and the number of sources available increased over the colonial period. I therefore restrict the sample to cover the period after 1600. Most of the variation in the data is from after 1750 when more data is available. At contact, numbers mainly come from Spanish reports on military numbers, males in city-states, and written impressions by early settlers and conquistadors. However, once the administrative capacity was in place, the main data source is tribute counts. The motivation for these counts was fiscal and the relationship between total population and tributary count changed over time. In a few cases, I have used conversions between tributary counts and population numbers available in [Gerhard \(1993a\)](#). Some of the sources used report population data directly. This is typically the case for the second half of the 18th century. In addition to tributary counts, important sources that form the basis of the data used in the paper are from various civil, fiscal, and ecclesiastical records.

Following, [Arroyo Abad and Zanden \(2016\)](#) the starting point of the dataset is [Buringh \(2013\)](#). The basic criterion to select for inclusion into the database was the availability of historical data on its population size for the period between 1500 and 1800, minimal size of 5.000 inhabitants in 1850 was formulated (similar to what [Bairoch \(1988\)](#) previously applied as one of their inclusion criteria), minimal size of 100.000 inhabitants in 2000 has been used for inclusion into the database. If one of these criteria was met a city was included in the dataset. For these cities, the database is constructed using a variety of secondary sources. I supplement and extend this dataset using a range of sources. Data on central Mexico is from [Gerhard \(1993a\)](#). Northern Mexico and the Southwestern United States is from [Gerhard \(1993b\)](#). Southern Mexico and parts of Guatemala are from [Gerhard \(1993c\)](#). For Peru I use information in [Cook \(1981\)](#). Data on Buenos Aires is from [Johnson and Seibert \(1979\)](#). Information on Colombia is from [Pinzón, Mora and Mora \(1994\)](#). Population numbers for larger cities I use numbers from [Morse \(1974\)](#).

An inevitable issue is that the reporting year often does not coincide with the 50-year bin in which the data is coded in the dataset. For example, for New Granada (present-day Colombia) the first proper census was conducted between 1777 and 1779. For most cases, I assign the observation to the closest 50 year period. Observations in 1790 would for example be assigned to 1800. If there are observations on either of the year of interest, for example, 1790 and 1805, I assume an average growth rate for every year and calculate the predicted population size in 1800. In particular, I use the following formula to extrapolate between year t and year t' , $(L_{t'} - L_t) / L_t \times \hat{t} \times L_t$, where \hat{t} denotes the number of years from t to the closest year recorded in the sample.

Settlements. Economic expansion, an increased military presence, and missionary activity also led to the formation of new settlements ([Morse, 1974](#)). Examples of settlements founded in this period that later grew into larger cities are San Francisco, Albuquerque, San Antonio, Montevideo, Copiapo, and Rancagua ([Morse, 1974; Parry, 1990](#)). To capture this, I further supplement the dataset territorial gazetteer of around 15,000 places that existed in the Spanish Empire during the 18th and early 19th-century ([Stangl, 2019](#)). The city (*ciudad*) was the highest legal denomination given a settlement in the Spanish Empire. The founding of cities were typically conscious efforts by the crown to ensure territorial control, rather than something which naturally occurred through population growth. Criteria for locations chosen depended on a range of micro-geographic factors such as ease of defense and water supply. Often these were founded in localities where large population centers already were located. Moreover, towns were in some cases upgraded from town status (*villa*) to city status. Few settlements with the status of city were founded during the study period, however, several settlements were founded that later would evolve into large population centers. The town (*villa*) was a legal status granted a settlement in the Spanish Empire. Also, the founding of cities were typically conscious efforts by the crown to ensure territorial control, rather than naturally occurring through population growth. The formation of new towns was frequent throughout the study period. The data

come from a variety of sources. "Sources include archival material like census tables, mission reports, visitations of dioceses and provinces, but also more ephemeral documents like petitions of some city council which was mostly not written for giving geographic information but may touch one specific detail or incidentally exposes some relevant information. Non-archival contemporary sources include mostly highly systematic sources for information like so-called "Foreigner Guides" (printed calendar-manuals which included also lists of office holders of many parts of the Empire), maps, or geographical descriptions both printed and manuscripts." ([Stangl, 2018](#)). Around 11 percent of cell/decade combinations have a settlement in the main dataset.

Potential vegetation. Global potential vegetation data is from the Center for Sustainability and the Global Environment (SAGE). The data is representative of the world's "potential" vegetation, that is vegetation that would most likely exist now in the absence of human activities. The data consists of a global map of natural vegetation at a 5 min resolution classified into 15 vegetation types. These are:

- Tropical evergreen forest/woodland
- Tropical deciduous forest/woodland
- Temperate broadleaf evergreen forest/woodland
- Temperate needle leaf evergreen forest/woodland
- Temperate deciduous forest/woodland
- Boreal evergreen forest/woodland
- Boreal deciduous forest/woodland
- Evergreen/deciduous mixed forest/woodland
- Savanna
- Grassland/steppe
- Dense shrubland
- Open shrubland
- Tundra
- Desert
- Polar desert/rock/ice

The data is available at <https://nelson.wisc.edu/sage/data-and-models/global-potential-vegetation/index.php>. Details about the construction of the data can be found in [Ramankutty and Foley \(1999\)](#).

Agricultural yield. I use a measure of agricultural potential constructed by [Galor and Özak \(2015, 2016\)](#). The data measure the maximum attainable yield measured in calories that can be achieved for a variety of crops. Agricultural productivity is the maximum potential production capacity in tons per hectare over the seventeen crops

- Buckwheat
- Barley
- Chickpea
- Foxtail millet
- Groundnut
- Maize
- Oat
- Pearl millet

- Wetland rice
- Rape
- Rye
- Sunflower
- Soybean
- Sweet potato
- Sorghum
- Wheat
- White potato

Climate and temperature. Data on climate and temperature are from the WorldClim global climate database. The data spans (1960-1990) at 5-minute resolution. See <https://www.worldclim.org/data/bioclim.html> for the data source. The following variables are included in the analysis:

- Annual mean temperature
- Mean diurnal range (mean of monthly (max temp - min temp))
- Isothermality
- Temperature seasonality (standard deviation ×100)
- Max temperature of warmest month
- Min temperature of coldest month
- Temperature annual range
- Mean temperature of wettest quarter
- Mean temperature of driest quarter
- Mean temperature of warmest quarter
- Mean temperature of coldest quarter
- Annual precipitation
- Precipitation of wettest month
- Precipitation of driest month
- Precipitation seasonality (coefficient of variation)
- Precipitation of wettest quarter
- Precipitation of driest quarter
- Precipitation of warmest quarter
- Precipitation of coldest quarter

Ruggedness, slope, and elevation. The Terrain Ruggedness Index was developed in [Elliot, DeGloria and Riley \(1999\)](#) and follows the classification:

- 0-80 - Level terrain surface.
- 81-116 - Nearly level surface.
- 117-161 - Slightly rugged surface.
- 162-239 - Intermediately rugged surface.
- 240-497 - Moderately rugged surface.
- 498-958 - Highly rugged surface.

- > 959 - Extremely rugged surface.

I measure ruggedness by the average standard deviation of elevation. Plains will score low in this measure, while mountains and valleys will score high.

C Further Historical Background

This section provides a more detailed historical background for the analysis. I discuss the background and the motivation for the trade reform as well as the historical relationship between trade and economic development within the Spanish Empire.

A central aim of commercial policy in the 18th century was to promote state wealth acquisition through trade surpluses ([Findlay and O'Rourke, 2007](#)). In the Spanish context, this was achieved through a range of policies restricting trade. First, trade was restricted to four ports in the Americas (Cartagena de Indias, El Callao, Portobello/Nombre de Dios, and Veracruz) and only Seville/Cádiz in Europe. Further, the frequency of travel and the routes were restricted. Typically, only two fleets left Spain every year: the New Spain *flota* destined for Veracruz, and the *Tierra Firme galeones* destined for Cartagena and Portobello. In the Pacific, shipping was conducted by *Armada del Sur*, which carried goods from the trade fairs in Portobello to Pacific ports in South America ([Walker, 1979](#)). Moreover, the Manilla galleon would sail between Acapulco and Manilla. Official information was carried by *aviso* ships, which were light carriers operating separately from the commercial system and were not permitted or equipped to carry freight. Third, participation in Atlantic trade was restricted to Spanish merchants. Finally, there were high tax rates on imports and exports. The duties typically depended on the origin of the goods, with lower rates on goods originating from Spain. These measures effectively monopolized trade in the merchant guilds in Seville (later Cadiz), Mexico City, and Lima, and only the merchant guilds of these cities were allowed to buy and sell goods at the trade fairs at Veracruz and Portobelo. These locations then in turn managed trade with other locations in their respective viceroyalties, typically transported by third parties using mule trains (*recuas*) or wagons (*carros*) depending on road conditions. The system limited trade with Europe across large parts of the Spanish empire in America, however, there was still some maritime communication and trade occurring in locations too remote relative to the large trade routes. In addition to dispatch ships (*avisos*), ships sailing under special permission of the crown (*registros*) occasionally supplied ports that were too remote relative to the large trade routes. However, this was never done at a sufficiently large scale ([Walker, 1979](#)) and increased the reliance on contraband trade which was sizeable ([Christelow, 1942](#)). While as a rule, there were no restrictions on inter-regional trade ([Elliott, 2006](#), p. 111), there were cases where inter-regional was discouraged. For example, there were policies in place to limit trade between the Viceroyalties of Peru and New Spain to reduce the demand for the goods of the Manilla Galleon in Peru. Another example is the erection of a customs barrier in Córdoba (Argentina) in 1618 ([Scobie, 1971](#), p. 53).

Mercantilist restrictions and high trade costs ensured that trade was limited to non-competing goods with a high value-to-weight ratio. Important exports during the period beyond precious metals were hides, tallow, sugar, indigo, and cochineal ([Rahn Phillips, 1990](#)). The slave trade was subject to different rules. Trade of slaves was allowed for British ships from early to the mid 18th century as a result of the treaty of Utrecht, the *asiento* ([Walker, 1979](#)). These measures facilitated naval defense of convoys and limited imports to the Americas, thus limiting the flow of bullion to other places than the Iberian Peninsula while keeping prices for Spanish exports artificially high. It also facilitated the managing of risk in a context where long shipping times and costly communication made it difficult to predict demand ([Baskes, 2013](#)). As a result, in addition to remittances directly controlled by the crown, private remittances to Spain were substantial ([Cuenca-Esteban, 2008](#)). However, a likely consequence of Spanish mercantilist policies

before the liberalization in the late 18th century was the underdevelopment of peripheral areas in America (Fisher, 1997, p. 73). There were few changes to this system until the second half of the 18th century but there were some notable changes. In return for the support of France during the War of the Spanish Succession, French ships were allowed to trade along the Pacific coast for some time. Moreover, as part of the treaty of Utrecht, the English were granted the right to send a ship of 500 tons to the trade fairs. Finally, the trade fair at Veracruz was moved inland to Jalapa.

Reforming transatlantic trade. Beginning in the 18th century, Spanish policymakers were induced by geopolitical considerations, originating mainly in Europe, to overhaul the external trading system (Elliott, 2006). In the immediate aftermath of Spain's defeat in the Seven Years' War, a special *junta* was appointed under Charles III to "review ways to address the backwardness of Spain's commerce with its colonies and foreign nations" Stein and Stein (2003). Drawing on ideas for reforming the system of government in America that had been circulating for a long time, the *junta* proposed the abolition of the Cádiz monopoly as well as the fleet system. Further, it proposed opening 14 ports on the Iberian Peninsula as well as 35 ports in the Americas (Fisher, 1997). The ports that were opened on the Iberian peninsula in this period was Malaga, Almería, Cartagena, Alicante, Tortosa, Barcelona, Santander, Gijón, La Coruña, Palma de Mallorca, Santa Cruz de Tenerife. While the reform is believed to have a role in promoting the rise of the Barcelona textile industry, in the early 19th century, around 80 percent of Spanish trade with the Americas still went through the port of Cádiz (Fisher, 1997). Several ports in the Caribbean were opened already in 1765. Santo Domingo, Puerto Rico, Margarita, and Trinidad were opened for direct trade with Spain in 1765. Further, reform was slowed by the Esquilache riots in 1766, and the liberalization measures culminated in the decree of free trade in 1778, which opened several of the remaining ports. This was with the exception of Venezuela (Caracas), where it was believed the Caracas companies tobacco monopoly was worth protecting, and New Spain. Even so, especially Veracruz was affected by the changes before the late 1780s due to the abolition of the convoy system and the increased prevalence of register ships. In the 1780s, the remaining ports followed. Spanish communication with the Americas was disrupted during the Napoleonic wars (O'Rourke, 2006). Out of necessity, trade with neutral nations was therefore allowed. This marked the end of Spain's ability to enforce protected trade with the colonies. By the beginning of the 19th century, Spanish America enjoyed *de facto* although not *de jure* unrestricted trade with foreigners (Fisher, 1998). As a result, direct trade with Britain, not mediated through Spain, grew in importance (Prados de la Escosura and Casares, 1983). Independence was mostly followed by high tariffs, mainly driven by the revenue needs of post-independence governments (Coatsworth and Williamson, 2004).

The historical literature emphasizes the role of European interstate competition and the resulting increased need for a modernized imperial defense as motivating the reform. Thus, the drive to reform the Spanish commercial system can be understood as being motivated by the intense interstate competition between the European states of the 18th century (Kuethe and Andrien, 2014). Highlighted in the historical literature as an important impetus for the reform was the "humiliating" capture of Havana and Manila by the British during the Seven Years' war. This opened a window of opportunity for reform-minded policymakers in Spain who now could justify reforming the commercial system with concerns about the territorial integrity of the empire in what has been described in the historical literature as a "defensive modernization" (Stein and Stein, 2003). Furthermore, the commercial expansion of Havana during the British occupation showcased the economic potential of the Spanish colonies.

The reform was therefore implemented rapidly after the Seven Years' War (Fisher, 1997). As a result, the timing of the reform is mainly driven by intensified interstate competition in Europe, rather than economic development in the Americas directly. Moreover, the reform was implemented from above, and no significant ports in which the policies were applied were excluded. This is also apparent from the fact that the policies were resisted by powerful interests in the Spanish Empire (Baskes, 2013). Finally, the selection of ports is unlikely to be driven by the perceived

commercial potential of its hinterland. This is apparent when considering the case of New Spain. As the most important colony of the Spanish empire in America, it was believed New Spain would have diverted too much trade away from other regions ([Fisher, 1997](#)). Moreover, avoiding confrontation with merchants in New Spain whose resources was a key source of revenue for the crown. As a result, New Spain was not subject to the reform until the late 1780s.

It is generally agreed upon that the reform increased trade. This was recognized by contemporaries as well as in the historical literature. Floridablanca (minister under Charles III and not a neutral observer) wrote about a fortunate revolution (*feliz revolución*) when referring to Spanish export growth after 1778. When referring to Veracruz, went from “gloomy and ugly” to “elegant and growing” ([Stein and Stein, 2003](#)). The magnitudes in the economic history literature are contested ([Cuenca-Estebar, 2008](#)). Colonial imports to Spain increased tenfold and exports from Spain to the colonies fourfold according to [Fisher \(1985\)](#), while more modest estimates are found in [Cuenca-Estebar \(2008\)](#), also suggesting large effects. However, while the reform stimulated trade, the terms of trade in many ports presumably remained depressed ([Francis, 2017](#)). [Fisher \(1993\)](#) provides data on the composition of Spanish imports from Spanish America between 1782 and 1796 for the ports of Cadiz and Barcelona (which accounted for around 88 percent of imports from Spanish America). Precious metals still accounted for 56.4 percent of imports through this period. The other commodities were typically high-value agricultural commodities (tobacco 13.6, cacao 7.8, sugar 5.5, indigo 5.2, cochineal 4.2, hides 3.4 and cotton 0.4 percent) ([Fisher, 1993](#)). Cadiz remained the dominant port for trade with Spanish America between 1778 and 1796 (76.4 percent of total exports and 84.2 percent of imports). The remaining important ports were Barcelona (9.6 and 3.8 percent), Malaga (4.8 and 1.3 percent), Santander (3.3 and 2.6 percent), and La Coruña (3 and 6.8 percent) ([Fisher \(1993\)](#) p.20 and p.25).

Some accounts highlight that the lower trade costs induced by the reform promoted agricultural development. “...for the first time, the metropolis succeeded in unleashing the agricultural potential of its American possessions whilst also promoting the continued expansion of mining production. The relationship between this economic growth and the liberalization of trade is abundantly clear”, ([Fisher, 1997](#), p. 197). Moreover, lower trade costs induced by unrestricted sailing potentially allowed for specialization in a wider range of commodities, such as more perishable goods. However, bullion remained an important export commodity ([Fisher \(1997\)](#), p. 38). Moreover, it has been argued that the population and economies of previously stagnant peripheral colonies in Spanish America grew rapidly ([Mahoney, 2010](#)). In summary, the historical literature suggests the restrictions imposed on trade in goods with the Americas stunted economic development, and efforts induced by European interstate competition to relax these marked the beginning of a process that would have large effects on trade and affect economic development in the second half of the 18th century.

D Figures

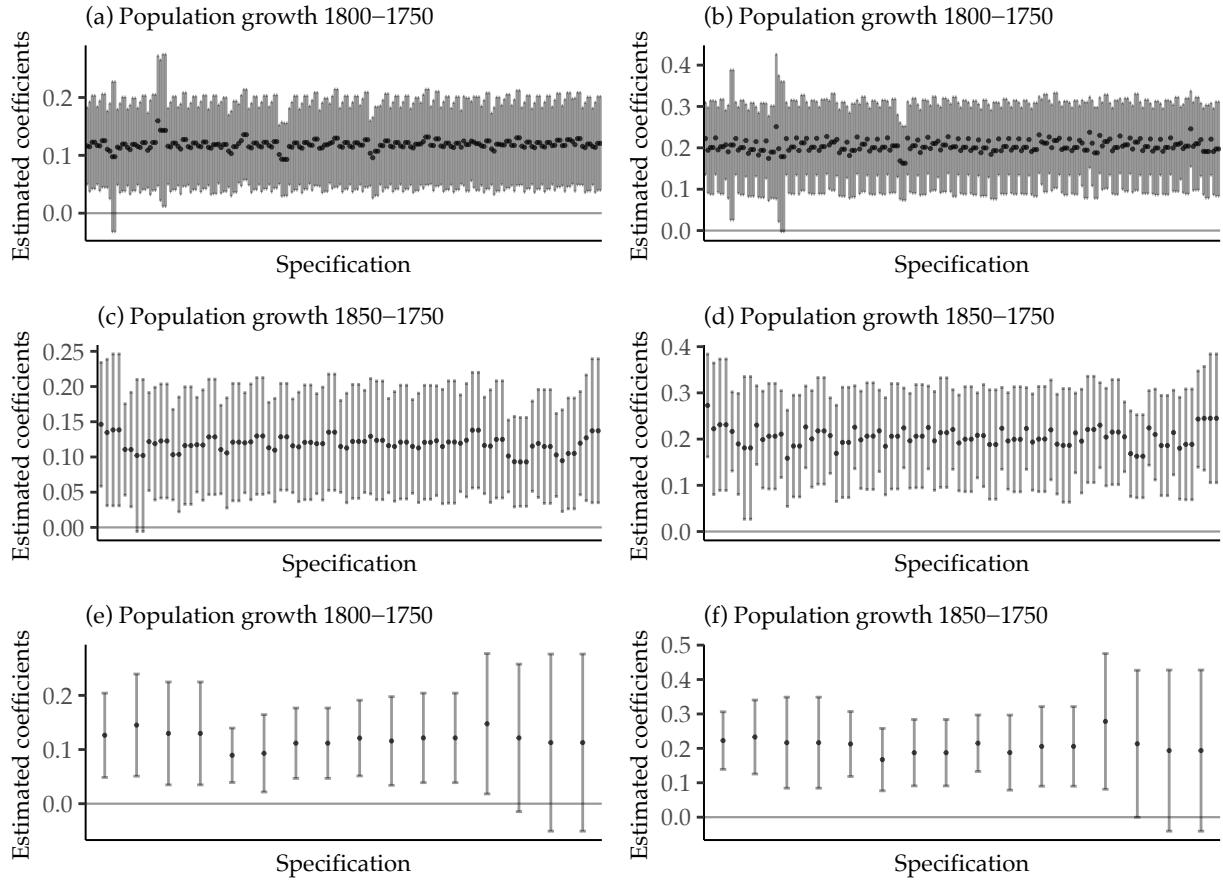

Figure A1: The figure shows the estimates in Table 5 for different subsamples. Panel (a) and (b) shows the model re-estimated after removing each port catchment area. Panel (c) and (d) show the model re-estimated after removing each country. Panel (e) and (f) show the model re-estimated after removing each viceroyalty.

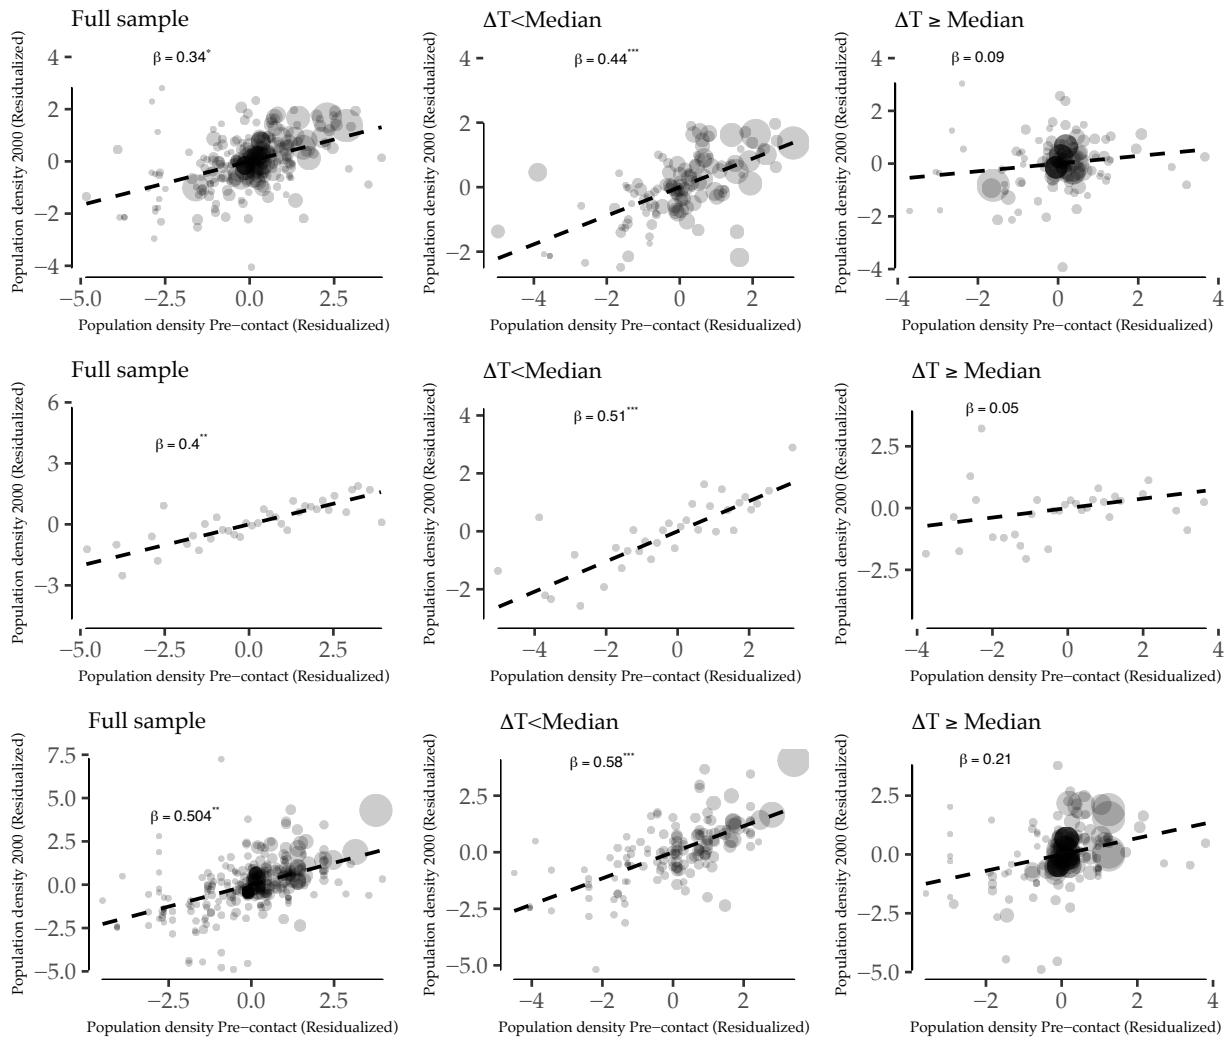

Figure A2: The figure shows the relationship between pre-contact population density and the population density in the year 2000 at the level of the province. The left figure shows the relationship for the full sample. The middle figure shows the relationship for provinces with a below median change in the distance to Europe between 1760 and 1810. The right figure shows the relationship for the sample above median reduction in shipping time to Europe between 1760 and 1810. Pre-colonial population density is the number of people per square kilometer pre-contact. The dependent variable is the log of people per square km in 2000. The full sample contains 337 observations. **Geographical controls:** Altitude, ruggedness, rainfall, and inverse distance to the coast (see [Maloney and Valencia \(2016\)](#) for details). **Standard errors** are clustered at the country-level.

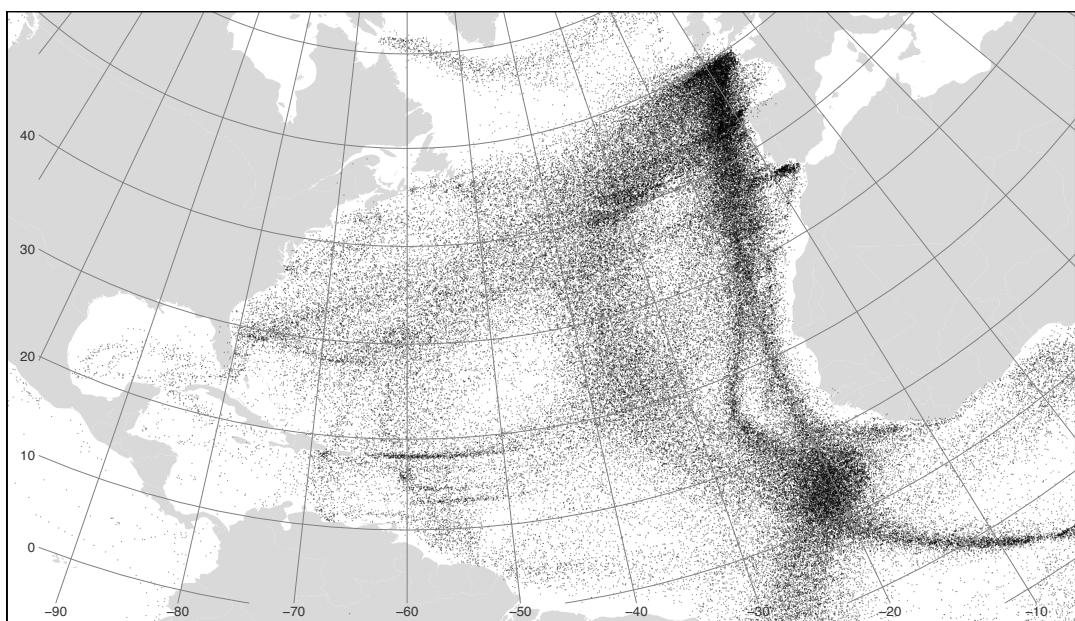

Figure A3: The figure shows the logbook entries used to estimate the travel times in the main analysis. Each dot represents a logbook entry between 1750 and 1850. Source: CLIWOC.

Audiencia FE				✓

Note: The table reports OLS estimates. Shipping time is standardized. The unit of observation is a city in a certain year. **Dependent variable:** The change in the natural logarithm of the city population. **Controls:** Elevation, crop suitability, the location of active mines, distance to the coastline. **Standard errors:** Clustered at the level of the closest port. *** $p < .01$, ** $p < .05$, * $p < .1$

Country FE			✓	✓
Controls	✓		✓	✓

Note: The table reports OLS estimates. The unit of analysis is the province. Pre-colonial population density is the number of indigenous people per square kilometer before the arrival of Columbus from [Maloney and Valencia \(2016\)](#). The dependent variable is the log of people per square kilometer in 2000. The full sample contains 258 observations. **Geographical controls:** Altitude, ruggedness, rainfall, and inverse distance to the coast (see [Maloney and Valencia \(2016\)](#) for details). **Standard errors** are clustered at the country-level. *** p < .01, ** p < .05, * p < .1

N	55,154	55,154	55,154	55,154

Notes: The unit of analysis is at a $0.5^\circ \times 0.5^\circ$ grid-cell. **Observations:** The dataset is a balanced panel at a 10 year frequency for the period 1710-1810 for 5,014 grid cells. The full dataset contains $11 \times 5,014 = 55,154$ observations. The omitted year is the year prior to the treatment (1760). **Controls:** Distance to the coast (log), elevation, presence of an active mine, terrain ruggedness, and crop suitability. **Standard errors:** Clustered at the level of the closest port. *** $p < .01$, ** $p < .05$, * $p < .1$
